ALICE E. BUCK.

PALPABLE EPITROCHLEAR GLANDS

SIR,—Surveys and tables no doubt have their uses, and Dr. Laurence Martin's dip into the literature of syphilis (March 22, p. 363) has its interest; but clinical medicine does not work like that when it deals with a problem, such as a patient with a suspicious lesion of the tonsil. It is then that palpation of the epitrochlear lymph-nodes has its value. *If the glands are palpable on both sides you must go on* and withdraw blood for a Wassermann reaction whatever the domestic implications may be. The diagnostic *value of the epitrochlear nodes* lies in the fact that they are the only superficial ones which are not fairly frequently palpably enlarged in healthy people. You find those in the groin enlarged in people that walk a lot, those in the axilla in people with sweaty arm-pits, those in the neck in adults in whom they are left over from the physiological recurring enlargements of childhood; Dr. Martin finds that he can palpate a normal epitrochlear lymph-node; I cannot. When there is a general enlargement of the lymph-nodes throughout *the body*, I can feel this gland; and one of the conditions in which this occurs is secondary syphilis, where it may be palpable before there is any rash.

If, then, a person has a suspicious lesion on the tonsil and both epitrochlear lymph-nodes are palpable you must follow up the line of inquiry. It is not a question of making a diagnosis on these findings alone. In the old days the inquiry consisted in asking the patient to show the external genitalia and waiting for further secondary symptoms. Today it is taking a Wassermann. In the 39 years in which I have followed and taught this traditional advice I must have felt for enlarged epitrochlear glands in quite 300 people who turned out not to have syphilis, *but I do not remember one* i whom I could feel them *on both sides.* On one side I have felt them from a small infective lesion of the little finger; but *in my experience* these septic lesions are not bilateral.

It is probable that in a throat department we are especially faced with this clinical problem; until about 1930 I used to have one example every three months or so and could go over the question with *each set of* dressers. Since then they have been very rare; but we have had one in a man during this three months. Perhaps the cases are going to the L.C.C. hospitals. During the war I saw three or four *at one* of these where I was then working, though none came to my clinic at Guy's. One was a young man sent up with a demand that I should erform tonsillectomy.

---

[1] Low, E. B., Davies, J. H. T. *Brit. J. Derm.* 1938, 50, 141.
[2] *Arch. intern. Med.* 1946, 78, 687.

It will be a pity, I think, if Dr. Martin's paper is nterpreted to mean that to palpate for epitrochlear ymph-nodes is of no clinical value in a suspected case of secondary syphilis.

Throat Department, Guy's Hospital. T. B. LAYTON.

RECURRENT SHOULDER DISLOCATION

SIR,—Until I read Mr. Hindenach's article on the interior bone graft (March 22) I had thought that this earsome operation had begun to be forgotten after its ecent revival.

The lesion in recurrent dislocation of the shoulder detachment of the capsule from the anterior aspect of the neck of the scapula) was first described by Perthes, who was treating the condition by suture as far back as 1906, and gives an excellent review of the problem.[1]

Mr. Hindenach appears to recommend the bone-graft operation when "the capsule is thin . . . or friable." I have never met this condition, nor does Perthes mention it in his article.

In this country Bankart popularised Perthes's operation, which is the only reliable procedure. The method of suture described by him is, however, unnecessarily difficult and traumatising. Recently there has been a return to Perthes's original method of using a steel staple (U-shaped nail of Perthes). An account of the method used in South Africa has been given by Sir Heneage Ogilvie[2] but even this method is needlessly traumatising; and I would refer Mr. Hindenach to a letter by me[3] describing an exceedingly simple approach to the anterior aspect of the neck of the scapula, sufficient to allow repair of the lesion using a staple introducer of the type described by Ogilvie and myself. Post-operative immobilisation is unnecessary; the patient need only be in hospital a few days; and there is a rapid return of function.

I hope the bone-graft operation will never become popular in this country.

London, W.1. J. S. MAXWELL.

ANTENATAL PREFERENCES

SIR,—As a prelude to a study of normal child behaviour in the borough of St. Pancras, it seemed worth surveying the preferences of husbands and wives for male or female children.

At antenatal clinics 100 married primiparæ, under thirty-five years of age, were questioned; 70 of the husbands were labourers or artisans and 30 were clerks, small shopowners, or skilled technicians: 31 women wanted a boy, 35 wanted a girl, and 34 had no preference. Of their husbands, 41 were said to want a boy, 32 a girl, and 27 to be indifferent.

Many factors influence the choice of sex for the firstborn. There is the influence of the parent's own family, for the children one knows best are oneself and one's siblings. No relation between predominance of siblings of one sex and preference for a firstborn of a particular sex could be proved in this small series, but several mothers cited their brothers or sisters as biasing their choice. The mate may have strong views: of the 50 couples, both members of whom held opinions, 30 agreed and 20 disagreed in their choice. The effect of topical events has probably been over-rated; although over a quarter of the primiparæ gave reasons for preferring a boy or a girl, only one mentioned war as a deterrent to bearing a boy. State custom in some races has encouraged selective infanticide of boys or girls[4]; but in England we have merely a mild patriarchal tradition.

One does not know if preferences vary in different social groups in this country, but male and female sex prestige seem approximately equal in the district where this study was made.

The 100 secundiparæ who were also questioned had borne 53 boys and 47 girls. Of the husbands, 70 were labourers or artisans, and 30 clerks, &c.: 60 women wanted a child of different sex to that of the firstborn, 24 were indifferent, and only 16 wanted a child of the same sex; 64 men wanted a child of different sex, 21 did not mind, and 15 wanted a child of the same sex as the first. 54 couples agreed and 11 disagreed in their choice.

It is interesting that the desire for a mixed family is so strong despite the economic disadvantages (e.g., waste of clothing and sleeping accommodation).

How do these preferences vary in different social groups? To what extent do they affect family planning? And how much do they influence the subsequent relationship of parent and child? RICHARD MEYER.

Maternity and Child Welfare Department,
St. Pancras, London, N.W.1.

MACROCYTIC ANÆMIA: A CORRECTION

SIR,—I write with all haste to disclaim the suggestion in the report (March 15) of a recent meeting of the Association of Clinical Pathologists that I described two cases of "pernicious anæmia" in which hydrochloric acid appeared in the gastric juice after treatment with folic acid.

One of the cases was of a young man who developed a macrocytic anæmia after resection of a long stretch of small bowel; the other of a young woman in whom a similar anæmia appeared after pregnancy. In both cases intractable diarrhœa was a prominent symptom; and in both the anæmia was irresponsive to liver.

I have on various occasions maintained both in speech and print that responsiveness to liver is an essential criterion for the diagnosis of pernicious anæmia. I regarded neither of these cases as falling within this category. S. C. DYKE

Director, Pathological Laboratories.

Royal Hospital, Wolverhampton.

PERFORATED PEPTIC ULCER TREATED WITHOUT OPERATION

SIR,—While the work of Mr. Hermon Taylor may make all previous ideas of the treatment of perforated peptic ulcers of historical rather than practical importance, my experience with conservative treatment in the last three years may be of interest.

Two problems have presented themselves in dealing with these sealed ulcers—diagnosis of the perforation and the indications for conservative treatment. The diagnosis of a sealed perforation is made on the same lines as the usual type, but because the symptoms are much less definite many cases are probably missed. The two most reliable symptoms are sudden onset of upper abdominal pain, which is invariable, and shoulder pain, which occurs in the great majority. The combination of these two symptoms should suggest a perforation, even if the rigidity is minimal. The signs may be very slight, particularly if the case is not seen for some hours, but there is always some rigidity and tenderness in the right upper quadrant. The diagnosis can be confirmed but not excluded by a straight radiogram taken after the patient has been sitting up for a few minutes.

The following rules have been evolved for deciding to treat a case conservatively. (1) At least one quadrant of the abdomen, usually the left lower, must show slight rigidity. (2) The area of board-like rigidity must be less than one complete quadrant. (3) The patient's general condition must be good and the pulse-rate less than 100 per min. when he has settled down after admission. All the cases treated conservatively have had a gas bubble less than 2 in. in depth.

At first these patients were kept strictly in Fowler's position, but in the last two years they have been treated in the most comfortable position. Nothing is given by mouth until the form of treatment has been definitely decided. The pulse is recorded half-hourly, and the abdomen examined every hour for four hours. If the ulcer is sealed there is a well-marked improvement within two hours; the pain diminishes, and the rigidity recedes towards the right costal margin. Within four hours a definite decision to operate or to treat conservatively is taken. The patient is put on a slow rectal drip, and allowed sips of water by mouth. The possibility of a further leak must always be considered, so he is not given any morphine for at least twelve hours, and any increase in pain or rise in pulse-rate must be reported. I have never been faced with the necessity of considering a change in the line of treatment once it has been started. After twelve hours the patient is allowed an ounce of water hourly, and this is increased until he is on an ulcer diet after four days.

[1] *Dtsch. Z. Chir.* 1925, 194, 1.
[2] *Brit. med. J.* 1946, i, 362.
[3] *Ibid*, p. 588.
[4] Ploss, H. H., Bartels, M., Bartels, P. Woman, London, 1935, vol. I, p. 548.

In the last three years among 42 consecutive cases diagnosed as perforation, 9 have been treated conservatively. There have been no deaths and no residual abscesses, but it is unlikely that there would have been any mortality in this type of case if they had been sutured. One case in which the above indications were exceeded gave anxiety for forty-eight hours, but then recovered uneventfully. The morbidity has been greatly reduced. The patients are over the perforation in four to five days, and gastric investigations can be started after seven days.

All forms of peptic ulcer will seal themselves. The series described is too small for analysis, but there have been both gastric and duodenal ulcers, and, in the cases of this type explored and found sealed before the conservative line of treatment had been adopted, there were all stages from acute ulcers, with a very short history, to old sclerotic ulcers with a long definite history.

Unfortunately the importance of the proximity of the last meal was not realised, so no records have been kept. Gastric suction has not been employed, but I consider that it would have greatly extended the scope of the conservative method.

Gloucester. P. M. BIRKS.

TEMPORARY HYPERTENSION AFTER CURARE

SIR,—A slight rise in blood-pressure after the administration of curare has already been recorded [1] [2], and we have often seen cases where a rise in pressure of up to 30 mm. Hg has followed its use, whatever method was used for the accompanying narcosis. Recently we were perturbed to encounter the following case:

> A man, aged 71, exceptionally fit for his age and with a blood-pressure (B.P.) of 160/90 mm. Hg, was undergoing colectomy for carcinoma. After premedication with morphine gr. $^1/_6$ and atropine gr. $^1/_{100}$ anæsthesia was induced with 0·25 g. 'Intraval,' and a no. 8 Magill tube was passed blindly, under light cyclopropane anæsthesia, after the soda-lime had been cut out of the circuit for a few breaths. 15 mg. of 'Tubarine' was given intravenously just before he was taken into the theatre, a little cyclopropane later being added to the circuit from time to time for maintenance.
>
> At the beginning of operation the B.P. was 140/90 mm. Hg and the pulse-rate 80 per min. After half an hour the pressure rose suddenly to 180/120 and continued to go up steadily, twenty minutes later reaching 200/110; fifteen minutes after this the beat could be heard at the extreme top of the sphygmomanometer scale, giving a reading of at least 260/120. All these abnormal systolic readings were confirmed by palpation of the radial pulse. Thirty-five minutes later the pressure dropped to 200/110, and after a further twenty minutes it was 160/100. The pulse-rate had remained between 80 and 100 throughout, and the patient left the table, after $2^1/_2$ hours' anæsthesia, with a blood-pressure of 180/110 and a pulse-rate of 90. Removal of the mask revealed that a profuse epistaxis had taken place, which, we must hasten to add, had not appeared immediately after the passage of the tube. The patient's reflexes returned while he was still in the theatre.
>
> Postoperatively he showed no untoward effects of his temporary hypertension. The night following operation his pulse-rate was 64 and of normal volume, no reading being taken to avoid disturbing him. The following morning his B.P. was 160/90, at which it remained until his discharge.

During the operation there was neither gross respiratory depression nor anoxia; the soda-lime was fresh and, indeed, was changed as a precaution as the blood-pressure rose; and we were certain the narcosis was not too light. The sphygmomanometer was subsequently checked. We concluded that curare was responsible for this alarming rise in blood-pressure; that the epistaxis indicated the functioning of a most auspicious "safety-valve", and that the pharmacology of curare can certainly bear closer investigation.

INFORMING THE PATHOLOGIST

SIR,—In many teaching hospitals the study of c pathology is much restricted, and pathologists e can usually tell at once whether a new houseman has taught how to use a laboratory. It is perhaps not be expected that this ancillary though all-emb branch of medicine should receive much attention in already overburdened curriculum; but there are think, some simple ways in which the student could made aware of the importance of an efficient approach the laboratory, and of the benefit that could acc to him through such an approach.

Often request forms submitted to the laborat are badly filled in, causing irritation and delay. could quote many examples: for instance, a requ for a blood-count accompanied only by the diagn "fractured femur" does not get anyone very far; extra few words—"clinically anæmic" or "P.U.O" would raise the status of the request form from t of a penny-in-the-slot to a reasonable medical docume Similarly with histological requests: "tumour of leg—section please." The pathologist at once wond how big it is, how long present, and whether it easily removed. In his own hospital the patholog can overcome these things by personal contact with houseman, but when specimens arrive by post furth information may be difficult to obtain.

Would it not be possible for every student to spe at least one full working day in a clinical patholog laboratory, perhaps at about the end of the second mo in the medical wards or sooner? The purpose of th would be simply to show him what happens to specime when they arrive at the laboratory. Seeing the for that accompany them, he would appreciate the value filling them in correctly with essential clinical detai He would come to understand that the purpose of t form is not just to enable the specimen to travel fro the ward to the laboratory. Even if he learnt no clinic pathology he would at least have learnt the corre approach to the laboratory; and possibly his inter might be stimulated.

One more point. The making of blood films is simp when properly done; but it rarely is properly done clinicians. A good blood film is essential where blo for counts has unfortunately to be sent by post. Af all, the blood film is usually the most important sta of a blood-count. The pathological service is to extended, and even the smallest coöperation between t clinician and the laboratory will increase its value.

Canterbury. I. B. MORRIS.

Parliament

QUESTION TIME

What We Eat

Mr. W. ELLIOT asked the Minister of Food what intake calories per head per day was shown, for the latest availa month, by his department's dietary food survey; and wh were the comparable figures for the corresponding month 1946.—Mr. J. STRACHEY replied: Our latest available fig is for November last. It is based on a small but representati sample of working-class families. It covers only food eat in the home, and not, for example, school or canteen mea The figure is 2320 calories, which shows no variation from t figure for November, 1945. It is very difficult to know wh addition ought to be made for meals taken out, but a cante meal will contain anything from 600 to 1000 calories.

Family Allowances Claims

Replying to a question Mr. JAMES GRIFFITHS stated th though the total number of families entitled to draw fam allowances was not precisely known, it was estimated th up to the present about 93% of the families initially entitl have received awards. Belated claims were still coming in.

Mr. JOHN LEWIS asked the Minister of National Insura if he would consider introducing amended legislation so th under the Family Allowances Act, claims by parents family allowances should not be affected by their havi children over the age of 14 years who were mentally defect or incapacitated and who were not included in the catego of those undergoing full-time instruction in a school virtue of the Family Allowances (Qualifications) Regulati

1946.—Mr. Griffiths replied: I sympathise with his point but a number of anomalies would arise if this particular type of case were picked out for special treatment. The Family Allowance Scheme has only been running for just over 6 months and I think we must have more experience of its working before we contemplate further legislation.

Industrial Injuries

Mr. D. J. Williams asked the Minister whether he had received the report of the Interdepartmental Committee on the Assessment of Disablement due to Specified Injuries; and what action he intended to take in the matter.—Mr. Griffiths replied: I have considered the recommendations of the committee and I am prepared to accept them in principle as a basis for the regulations which I shall have to make regarding the assessment of injuries under the Industrial Injuries Scheme.

Doctors in the R.A.F.

Mrs. Ayrton Gould asked the Secretary of State for Air if he was aware that the proportion of medical officers to officers and other ranks in the R.A.F. was 30% higher now than it was at the end of the European war: and if he would take steps to reduce the proportion of medical officers to other personnel in the Service to the war-time level.—Mr. Philip Noel-Baker replied: I am aware that the proportion of medical officers in the R.A.F. is higher now than at the end of the war. There are some good reasons why this should be so, but I share, nevertheless, the preoccupations expressed by my hon. Friend. I propose to consider the matter again in consultation with my right hon. Friends.

Wortabet.—On March 15, in London, James Rashid Wortabet, M.B. Glasg., D.P.H.

Notes and News

SAFETY FROM SPARKS

The risk of anæsthetic vapours becoming ignited in operating-theatres may be still further reduced by the introduction of a new form of rubber which will be exhibited at the British Industries Fair. The commonest causes of ignition are the cautery, diathermy, electrical switches, or similar appliances; or the overheating, short-circuiting, or breakage of the small electric bulbs used in endoscopy. But the static electricity generated by friction between non-conducting blankets or mats is another possible cause which has proved very difficult to overcome. In one test drawing a blanket rapidly over a rubber mat on a trolley produced a static charge of 30,000 volts, giving a spark which would be fully capable of igniting ether vapour. In its draft warning notice, circulated to hospitals three years ago[1] by the Ministry of Health, the Operating Theatres Electrical Apparatus Committee recommended the fitting of trailing chains to all apparatus insulated by non-conducting tyres or pads, and some hospitals have practised humidifying the atmosphere. These cumbersome precautions may be superseded by the use of electrically conductive rubber. Conductivity has been achieved by adding to the rubber mix very finely divided carbon, which, while blackening the material, increases its resistance to wear and tear. To prevent the generation of static charges all rubber articles in the theatre must be of this material—its partial installation might increase rather than diminish the danger of explosion. This substance, devised by the Dunlop Rubber Co. Ltd., is a development from earlier work on antistatic tyres for aircraft.

DEODORANTS REVIEWED

In America, deodorants seem to be sold more freely than here, both to hospitals and private people. The research department of the Hospital Bureau of Standards and Supplies Inc., of New York, has published a useful survey by Mr. Dewey H. Palmer of common deodorants and deodorising equipment, assessing their value.

Three types of deodorants are widely sold—liquid vaporising types, ozone generators, and substances which act by adsorption. Mr. Palmer reviews five popular vaporising liquids, one of them selling to the tune of 4 million dollars a year. Such liquids form the greatest proportion of all deodorants sold to institutions, but chemical analyses and tests have shown that any effect they have is due to their covering odours. Some contain formaldehyde, which reduces the sense of smell slightly but also irritates the nasal mucosa. Chlorophyll, much advertised as an important component of others, has no deodorising properties at all; it will not even vaporise at ordinary temperatures: if it did, as one chemist put it, green clouds would rise from every kettle of spinach. Two of the products reviewed had been investigated by the U.S. Naval Medical Research Institute and found to be completely ineffective. Claims that such vaporising liquids work by chemical action and oxidation have been proved on test to be unfounded; any such action was too slight to affect strong odours.

Ozone generators are also found to be ineffective. The Council on Physical Medicine of the American Medical Association consider that the smell of ozone may mask other odours and also fatigue the olfactory nerves; but "contrary to aiding well-being, exposure to ozone may result in irritation of the mucous membranes of the nose, throat, and lungs, headaches, drowsiness, fatigue, and a burning sensation in the eyes." So much for the favourite seaside tonic.

The Naval Medical Research Institute report that activated carbon is the only agent capable of reducing or removing odours. The air must pass through a substantial quantity of activated carbon, being pumped or sucked through canisters by various devices; but adsorbent devices which depend for their effect on the natural circulation of air are not a success. For foul-smelling wounds or other local physical troubles associated with smell the most successful method is pronounced to be the use of filter cloth, impregnated with activated charcoal, which was first described in The Lancet in 1942 (vol. i, p. 755). This can be cut to any shape and applied over dressings, or made into boots or other garments to cover and enclose an infected area.

Mr. Palmer concludes that washrooms and toilets can best be deodorised by frequent cleaning with soap and water,

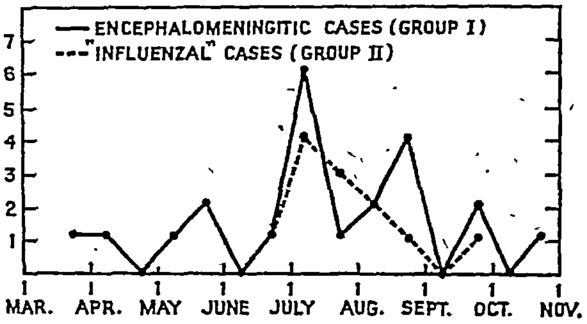
ar included 2 patients with cerebral symptoms compatible
with a mild encephalitis.

CLINICAL PICTURE

Most of the cases were in children or young adults. The illness usually began suddenly with fever and frontal headache, but there was in many of the cases about a week's prodromal period of fluctuating fever and headache before the onset of the more severe symptoms, and this was sometimes accompanied by increased fever and by shivering. But, though meningitic manifestations (headache, vomiting, photophobia, and stiffness of the neck) were almost constant at this stage, they were sometimes not well marked; neck stiffness was often very moderate and at times even so slight as not to be noted by anyone not looking specially for it. It was thus often quite difficult to draw a clear-cut line between prodromal and meningitic symptoms. Difficulty in diagnosis was also caused at first by the patients with normal cerebrospinal fluid (C.S.F.) who, like those just described, had severe headaches and very moderate neck stiffness—e.g., cases in group II and case 19 at the outset.



Half-monthly incidence of encephalomeningitic and "influenzal" cases (1 case in November and 1 case in December omitted).

Case 17 was admitted on the twenty-first day of his illness, case 4 on the fifteenth, case 2 on the tenth, and 9 patients in group I on the sixth or seventh day. The remaining patients in group I were admitted on the third or fourth day of the illness, and case 19 did not show C.S.F. changes until a few days after admission. Furred tongue and anorexia were common in the early stages, but faucial inflammation and coryza were uncommon. Diarrhœa and constipation were prominent in 3 or 4 cases. Only in 7 of the cases in group I did the prodromal phase appear to be absent.

The increased severity of headache, which probably often marked the onset of the meningitis, was apparently the determining factor in causing the admission to hospital of many of the patients, but in 5 children and 1 adult symptoms suggesting encephalitis (apathy, twitchings, severe drowsiness, delirium) were the main symptoms; headache and meningeal signs were less severe in these cases.

A striking occasional feature was the cranial-nerve weaknesses seen. In 4 cases there were unilateral facial palsies (supranuclear in case 7); in case 1 the auditory nerve was also involved, and in case 6 the hypoglossal nerve, in each case on the same side as the facial nerve involvement. In case 5 the internal strabismus improved rapidly: but the facial-nerve weakness recovered very slowly and still persists in 2 cases. Transient diplopia was noted in case 1, and 2 other cases showed slight nystagmus at first.

Case 1 had transient weakness of the right side of the body, cerebellar symptoms, and extreme giddiness. Three children during convalescence had rather prominent leg weakness with increased tendon reflexes, and it is possible that in these cases at least there was myelitis as described by Findlay et al. (1936). Sensory or sphincteric disturbance was not observed in our cases.

After admission the course of the illness was variable, but in most cases there was fever for about a week, and in many cases it was of low grade (99°–100° F). Several cases had temperatures of 102° F for the first two or three days, and in case 18 temperatures of 103° and 104° F were recorded. In case 8 there was low-grade fever for four weeks. Usually all signs and symptoms had disappeared by the end of the febrile period, but this was not true of the facial palsies: nor was it true in some of the more severe cases—e.g., cases 4 and 10. The temperature fell by lysis in all cases.

Leucocyte-counts were done in nearly all cases, and, though slight leucocytosis or slight leucopenia was seen in both groups, there was usually little abnormality in most counts. In a few of the abortive cases (group II) there was slight leucopenia and a relative lymphocytosis, but in no instance did the count strongly suggest infectious mononucleosis.

Paul-Bunnell and Widal tests, done in some cases, were negative.

The C.S.F. findings (table I) were used arbitrarily to divide the cases into group I, with positive findings, however slight (the meningitic and encephalomeningitic cases) and group II, with negative findings (the abortive, "influenzal," or non-meningitic cases). Case 35 in group II might be regarded as an intermediate case. Another case seen recently and not included in the series was also of this intermediate type. Here well-marked neck rigidity was associated with a blotchy rash on the limbs and with conjunctival and faucial injection; the C.S.F. contained 7 lymphocytes per c.mm. and 40 mg. of protein per 100 c.cm.

To illustrate the general pattern of the outbreak sample case-records are given from group I; and, though all these cases showed meningitic signs, they are subdivided, for convenience of description, into those which also had encephalitic symptoms or cranial-nerve palsies and those in which the meningitic signs predominated. This subdivision is an artificial one, since many of the "meningitic" cases had transient extensor plantar responses. In the same way the cases of group II have been put together for descriptive purposes and without implying a clear-cut pathological distinction.

GROUP I—ENCEPHALOMENINGITIS

Cases with Encephalitic Symptoms or Cranial-nerve Palsies

Case 1.—A woman, aged 47, was admitted on March 27, 1946, with a history of sudden onset of pain round rt ear, tinnitus, giddiness, and vomiting on the 20th, and two days later, rt facial weakness (lower motor neurone), and general weakness on rt side of body (reported by her doctor). Rt side of face felt numb for a short time. Some mental confusion and sphincteric incontinence before admission.

On admission she was rather drowsy and uncoöperative; unable to sit up, because of extreme giddiness; slight neck stiffness; Kernig negative; complete rt facial palsy (lower-motor-neurone type); nerve deafness of rt ear (drum normal); no facial sensory loss; no loss of power or of coördination in limbs; doubtful loss of tone on rt side of body; rt ankle-jerk definitely depressed, and doubtful extensor rt plantar response; all other tendon-jerks brisk, but abdominals absent.

C.S.F. (April 2): pressure 40 mm. H_2O; faint opalescence; total protein 20 mg. per 100 c.cm.; Pandy, faint trace; Wassermann reaction negative; polymorphs and lymphocytes 100 per c.mm.; sterile.

Further Course.—Very slow progress. Gradually able to sit up, with decreasing giddiness and lessening tendency to vomit on movement. Showed tendency to past-pointing to right for a time, and also brief period of diplopia on looking to left. Rt facial palsy and deafness very persistent. After a week tendon-jerks were all very brisk, and knee-jerks exaggerated (lt > rt). Plantars, lt flexor, rt extensor. After two weeks knee-jerks were less exaggerated, and plantars were both flexor.

C.S.F. (April 25): pressure very low; clear; total protein 20 mg. per 100 c.cm.; Pandy negative; 18 lymphocytes per c.mm.; sterile.

Much less giddy by end of first month, and after six weeks began walking. Great tendency to reel in either direction at first, but later deviated more to rt side.

Later made gradual improvement with instruction in walking and now gets about very well. Deafness in rt ear persists, as does much rt facial weakness, though this is still improving slowly (Nov. 8).

Case 6.—A boy, aged 4 years, was admitted on July 6 with a history of sudden onset of fever, sleepiness, apathy, and miserableness on the 5th. Also seemed to have pain in rt side of head, and a few hours before admission mother noted weakness of rt side of face.

On admission he was sleepy and apathetic; neck a little stiff and painful to flex; complete lower-motor-neurone lesion of rt facial nerve and deviation to right of protruded tongue; throat rather red, but nothing abnormal found in ears; temperature 101·4° F, pulse-rate 130.

Further Course.—Given short course of sulphadiazine for throat infection, and lumbar puncture done on second day of course.

C.S.F. (July 8): clear; pressure about 180 mm.; total protein 40 mg. per 100 c.cm.; Pandy, trace; chlorides 760 mg. per 100 c.cm.; lymphocytes 12 per c.mm.; sterile

White-cell count (July 8): 11,700 per c.mm. (polymorphs 45%, lymphocytes 47%, mononuclears 7%, eosinophils 1%)

Temperature fell to normal on third day, but drowsiness, miserableness, and apathy persisted two weeks. No weakness apart from rt facial weakness, and tendon-jerks all were definitely increased, especially on rt side. Plantars were flexor, but some bilateral withdrawal response was noted up to end of third week. Early walking caused leg pains, and progress at first was slow.

Follow-up (Oct. 8).—Now is very well, and only disability is a decreasing rt facial weakness of lower-motor-neurone type, though protruded tongue still deviates slightly to the right.

Case 7.—A boy, aged 4½ years, was admitted on July 9 with a history of having been tired and sleepy for three days before admission; two days before admission, from his mother's account, he seemed unable to walk, though "his legs did not look weak." On day of admission he fainted and showed weakness in the lower part of his face on the rt side

On admission he was alert and sensible; no headache, but unable to sit up, because of unsteadiness; neck stiffness; rt facial weakness of upper-motor-neurone type; cranial nerves otherwise normal, and no obvious weakness in limbs; Kernig negative; tendon-jerks increased in legs, particularly on rt side; plantar responses flexor, but withdrawal response of legs present on both sides; abdominals all present.

C.S.F. (July 9): clear; pressure 100 mm.; no block, total protein 40 mg. per 100 c.cm.; Pandy, trace; chlorides 700 mg. per 100 c.cm.; lymphocytes 31 per c.mm.; sterile.

White-cell count (July 9): 7900 per c.mm. (polymorphs 40%, lymphocytes 55%, mononuclears 4%, eosinophils 1%).

Further Course.—Made good recovery and became very active; soon lost neck stiffness; facial weakness diminished considerably, and emotional facial movements became normal; reflexes in limbs remained unchanged.

C.S.F. (July 17): clear; pressure 120 mm.; no block, total protein 40 mg. per 100 c.cm.; Pandy, trace; chlorides 720 mg. per 100 c.cm.; lymphocytes 7 per c.mm.; sterile.

Follow-up (August 15).—Only showed slight weakness on lt side of mouth during voluntary movement of facial muscles. Mother states that these muscles show involuntary spasms when he is excited.

Case 9.—A girl, aged 6½ years, was admitted on July 1 with a history of having been vaguely unwell, irritable, and off her food for a week; and of severe headache and photophobia for a day before admission, and of vomiting on the day of admission.

On admission she was flushed (temperature 103° F); herpes labialis; mentally clear and no headache; definite neck stiffness, but Kernig's sign negative; throat clear; nothing of note in any system, but tendon-jerks and abdominals were all depressed; plantars flexor.

C.S.F. (July 13): clear; pressure 200 mm.; total protein 20 mg. per 100 c.cm.; Pandy negative; chlorides 730 mg. per 100 c.cm.; cells 50 per c.mm. (lymphocytes 98%, polymorphs 2%).

Further Course.—Two days after admission temperature was falling to normal and child was comfortable; but, besides a persistent neck stiffness, she now showed a rt facial weakness of lower-motor-neurone type. The tendon-jerks were brisk; and, though the plantars remained flexor, there was an involuntary leg withdrawal response, more marked on the rt side. Subsequently the child made good progress, but occasional headaches and a little neck stiffness were noted during the first week.

C.S.F. (July 19): clear; pressure 170 mm.; total protein 20 mg. per 100 c.cm.; chlorides 740 mg. per 100 c.cm.; lymphocytes 12 per c.mm.

At discharge, rt facial palsy was little better, but child was otherwise well.

Follow-up (Oct. 22).—Fully recovered, apart from very occasional rt frontal headache; alert and well and free from facial palsy; all reflexes normal.

Case 10.—A boy, aged 3 years, was admitted on July 22 with a history of having been unwell and apathetic for a week before admission. No headache had been present, but parents had noted a tendency to muscular twitching during sleep. Persistent constipation.

On admission he was rather apathetic, apprehensive, and miserable; generally resistant to muscular movement and unable to sit up; held his back stiff if lifted, and kept hips and knees flexed; resistance to neck flexion, but no well-marked neck rigidity; Kernig's sign positive; knee-jerks slightly depressed, and ankle-jerks increased; plantars flexor; temperature 99° F; pulse-rate 120; otherwise normal, apart from a few enlarged glands in posterior triangles of neck; Mantoux 1 : 1000 negative; blood-sedimentation rate 7 mm. in 1 hour.

C.S.F. (July 21): clear; total protein 60 mg. per 100 c.cm.; lymphocytes 3 per c.mm.

White-cell count (July 22): 9000 per c.mm. (polymorphs 40%, lymphocytes 55%, mononuclears 5%).

Further course showed a persistent stiffness of neck and spine, and increased tone in the hamstrings, which led to the legs

TABLE I—C.S.F. FINDINGS IN ENCEPHALOMENINGITIC CASES

.. indicates that test was not done. Fluids sterile in all cases. Wassermann reaction, done in adults, always negative.

being kept in a "frog-like" position. The stiff muscles were tender but showed no atrophy. Tendon-jerks all became increasingly brisk during his stay in hospital, and the rt ankle-jerk gave an almost clonic response. (There was a notable tendency to hold rt foot plantar flexed.) Abdominals were absent, and the plantars difficult to obtain but probably flexor. Gradual lessening of pain and stiffness in back, leg, and thigh muscles, and gradual return of free movements. Simultaneous lessening of apathy and increased cheerfulness.

C.S.F. (July 26): clear; pressure about 250 mm.; total protein 80 mg. per 100 c.cm.; Pandy positive; chlorides 730 mg. per 100 c.cm.; lymphocytes 6 per c.mm.; sterile.

C.S.F. (August 6): clear; pressure 150 mm.; total protein 40 mg. per 100 c.cm.; Pandy positive; chlorides 690 mg. per 100 c.cm.; 35 lymphocytes per c.mm.; sterile.

Follow-up.—After discharge, he gradually regained use of legs, and six weeks later (Sept. 30) was running about though a little unsteadily. Mother also thought that there was at that time a little unsteadiness in use of rt arm for fine movements. No muscular wasting, and all movements full and free. Some persistent exaggeration of ankle-jerks, especially on rt side, but both plantars definitely flexor. Ultimately made complete recovery.

Case 11.—A girl, aged 6 years, was admitted on July 29 with a history of sudden onset of severe frontal headache and temperature of 102° F six days before admission. Intermission in fever and headache had followed for two days, but in last three days before admission there had been fever and increasing headache and drowsiness. Delirium on day of admission.

On admission she was very drowsy and hard to rouse for first three days in hospital; neck stiffness, but Kernig negative; no cranial-nerve abnormality apart from slight nystagmus; no wasting or loss of muscle power; tendon-jerks all brisk, apart from lt knee-jerk, which was slightly depressed; plantars both extensor.

White-cell count (July 29): 15,700 per c.mm. (polymorphs 74%, lymphocytes 20%, mononuclears 5%, myelocytes 1%).

C.S.F. (July 29): clear; pressure 180 mm.; total protein 30 mg. per 100 c.cm.; Pandy positive; chlorides 730 mg. per 100 c.cm.; cells 85 per c.mm. (lymphocytes 63%, polymorphs 37%); sterile.

Further Course.—Child brightened rapidly after first few days, and temperature was normal on third day in hospital. Neck stiffness not noted after first week in hospital, but tendon-jerks all became exaggerated; and, though plantars became and remained indefinite, there was a slight reflex leg withdrawal for about two weeks. Abdominals absent. Cranial nerves normal. Walking at first was unsteady; but, ten weeks after onset of illness, child is strong and active, although ankle-jerks are slightly increased and plantar responses remain indefinite.

C.S.F. (August 8): clear; pressure 80 mm.; total protein 40 mg. per 100 c.cm.; Pandy negative; 4 lymphocytes per c.mm.

Case 21.—A woman, aged 49, was admitted on May 12 with a history of having had headaches and giddy attacks for two years, but neurological investigations had been negative. Severe attack of vomiting in the morning was rapidly followed by unconsciousness, and she was admitted in light coma.

On admission she was febrile (temperature 103·2° F) and was semi-conscious and frothing at the mouth; could just be roused but made no further response; neck showed very slight stiffness; pupils small and not reacting to light; cranial nerves otherwise normal, slow athetoid movements of arms; tendency to flexion of arms, wrists, and fingers, but legs held firmly extended at knees, and feet plantar flexed; great increase in tendon-jerks, especially on the right; abdominal responses absent, and plantars indefinite; blood-pressure 140/80; nil of note elsewhere; skull radiogram normal.

C.S.F. (May 12): clear; pressure 230 mm.; no block; total protein 160 mg. per 100 c.cm.; Pandy positive; 1 lymphocyte per c.mm.; sterile.

Blood Wassermann reaction negative.

Further Course.—Patient recovered consciousness during the next two days, and pupil reaction gradually returned in this time. She was noisy on the third night in hospital, but thereafter rational. Temperature was normal on third day. Central nervous system on fourth day, apart from accentuated tendon-jerks in the legs (rt > lt) and an equivocal rt plantar response, was normal.

Early in convalescence an involuntary shakiness of arms was noted, but subsequently this disappeared and patient made a good general recovery.

Mr. T. G. I. James, of the Central Middlesex Hospital, kindly excluded any local lesion of the central nervous system before patient was discharged, and I am indebted to him for some of the later observations on this case.

The possibility of encephalitis lethargica was considered but thought improbable, since, according to Hall (1924), sudden onset is unusual and a high C.S.F.-protein level is rare in that infection. The good progress made up to Nov. 15 also, to some extent, supports the inclusion of the case in this series.

Cases Showing Predominantly Meningitic Signs

Case 2.—A man, aged 42, was admitted on April 11 with a history of very sudden onset of severe general headache, vomiting, and mental confusion on April 1. He had vomited for four days, and then symptoms had begun to abate.

On admission he was lucid; well-marked neck stiffness; Kernig negative; fine bilateral nystagmus; tendon-jerks all very brisk, but not much exaggerated; abdominals just present; plantars flexor.

C.S.F. (April 11): pressure 160 mm.; opalescent; total protein 400 mg. per 100 c.cm.; Pandy + + +; chlorides 620 mg. per 100 c.cm.; leucocytes + + + (lymphocytes 95%, polymorphs 5%); sterile.

Further Course.—Later cleared well, but showed transient depression of lt ankle-jerk and exaggeration of lt knee-jerk; final complete recovery.

C.S.F. (April 16): pressure 120 mm.; total protein 240 mg. per 100 c.cm.; Pandy + +; chlorides 690 mg. per 100 c.cm.; leucocytes 100 per c.mm. (lymphocytes 95%, polymorphs 5%).

Case 3.—A girl, aged 11 years, was admitted on May 27 with a history of fever six days before admission. After a brief subsidence, this had returned two days before admission, with rigor, frontal headache, and generalised muscular pains There had been intermittent, general, and severe headaches and vomiting on the day before admission.

On admission she was febrile; tongue furred; frontal headache and mental irritability; slight neck stiffness; Kernig negative; tendon-jerks all exaggerated; abdominals all very brisk; plantars both extensor; cranial nerves all normal, and no limb weakness; chest clear.

C.S.F. (May 27): pressure 120 mm.; slight opalescence total protein 30 mg. per 100 c.cm.; Pandy negative; chlorides 710 mg. per 100 c.cm.; cells 62 per c.mm. (lymphocytes 48% polymorphs 52%).

White-cell count: 10,200 per c.mm. (polymorphs 66% lymphocytes 28%, mononuclears 6%).

Further Course.—Rapid recovery; symptom-free after four days, and afebrile after one week; but tendon-jerks were still very brisk, and plantars both extensor. Even at discharge lt plantar was indefinite, though rt was flexor.

Follow-up (Nov. 5).—Has remained perfectly well, and reflexes are now normal.

Case 4.—A boy, aged 10 years, was admitted on June 11 with two weeks' history of occipital and nuchal pain, soon followed by pains in lower limbs. Neck pains associated with stiffness of neck muscles. Leg pains greatly accentuated by sitting up in bed.

On admission he was thin and weakly; temperature 99·8° F; tongue furred; no headache, but pain on attempted flexion of neck; very marked neck stiffness, and Kernig very strongly positive; stiffness of back muscles; cranial nerves all normal; no muscular wasting, and no loss of power or of coördination in limbs; all tendon-jerks depressed, apart from knee-jerks, which were very brisk; abdominals all present; but plantars indefinite.

C.S.F. (June 11): pressure 170 mm.; clear; no block; total protein 200 mg. per 100 c.cm.; Pandy + +; chlorides 730 mg. per 100 c.cm.; 1 lymphocyte per c.mm.; sterile.

Further Course.—Gradual slow improvement, but low intermittent fever, with evening temperatures between 98·4° and 99·4° F until sixth week in hospital. Became generally brighter and stronger, but neck stiffness was still just present two weeks after admission. Kernig's sign was still strongly positive at end of month. Only occasional headaches by then. Tendon-jerks remained very brisk, particularly on lt side, and though plantar responses were flexor there was tendency to a withdrawal response in lt lower limb almost up to time of his discharge. Chest normal.

June 12: white-cell count 10,400 per c.mm.

June 17: blood-sedimentation rate 6 mm.; Mantoux negative 1 : 1000.

TABLE II—DETAILS OF NON-MENINGITIC ("INFLUENZAL") CASES

.. indicates test not done.

Follow-up (August 24).—Very well and free from signs and symptoms. (For later examinations of C.S.F. see table I.)

Case 19.—A boy, aged 17 years, was admitted on Oct. 2 with a history of severe headache several hours after a fall from a ladder four days before admission. Head not appreciably injured. Anorexia and fever with the headache, and next day more severe headache and vomiting. Nausea and severe occipital headache persisted up to the time of admission.

On admission he was flushed and febrile (temperature 102° F); coryza, with suffusion of conjunctivæ; slight neck stiffness; some mental dulling; all tendon-jerks brisk; plantars probably both flexor; abdominals all a little depressed.

C.S.F. was under low pressure and showed no abnormality (table I). Skull radiogram normal.

White-cell count (Oct. 8): 7200 per c.mm. (polymorphs 59%, lymphocytes 33%, mononuclears 3%, eosinophils 5%).

Further Course.—Remained unwell for a week after admission, with temperature rising to 103° and 104° F in first five days. Frontal headache and mental dulling persisted in this period, and the neck stiffness and a positive Kernig's sign were just apparent. The central-nervous-system signs remained little changed, though the rt plantar at times showed an extensor tendency.

Lumbar puncture was repeated on Oct. 8, with now definite meningitic findings; slightly opalescent fluid; total protein 30 mg. per 100 c.cm.; chlorides 700 mg. per 100 c.cm.; polymorphs 350 per c.mm.; sterile.

Thereafter steady improvement was made; and, though slight stiffness of the neck and occasional frontal headaches were noted for another ten days, temperature became normal and remained so. Plantar responses also became definitely flexor, and patient appeared fully recovered four weeks after his admission.

Subsequent C.S.F. examination showed fewer cells and a preponderance of lymphocytes (table I).

Had occasional headaches for a short while after discharge; otherwise well.

Case 12.—A girl, aged 4 years, was admitted on August 16 with a history of general malaise, irritability, anorexia, and fever for seven days, and neck stiffness and drowsiness for a day.

On admission she was drowsy, but coöperative when roused; neck very stiff: Kernig positive only on rt side; no muscle wasting and no loss of power; tendon-jerks normal, and brisk abdominals; plantars flexor; throat clear; tongue clean; temperature 99° F.

C.S.F. (August 16): clear; pressure 100 mm., total protein 40 mg. per 100 c.cm.; Pandy, trace; chlorides 720 mg. per 100 c.cm.; cells 54 per c.mm. (lymphocytes 97%, polymorphs 3%); sterile.

Further Course.—Made good progress, quickly becoming afebrile and losing meningitic signs in four days; but rt plantar was extensor during the second half of the first week in hospital, and the knee-jerks were very brisk at this time. Fully recovered by discharge (Sept. 4).

C.S.F. (August 31): clear; total protein 40 mg. per 100 c.cm.; Pandy, faint trace; 3 lymphocytes per c.mm.

This last case might be taken as characteristic of the predominantly meningitic cases, those not described here in detail showing similar courses and signs.

GROUP II—NON-MENINGITIC CASES

There were 13 cases (table II) in which the symptoms and signs were very similar to those just described, but the changes in the C.S.F. (when this was examined) were absent or so slight as to have little diagnostic weight. These cases were again largely in children and young adults, and headache and slight stiffness of the neck were again the chief features in a brief febrile illness usually of sudden onset. Sore throat and coryza occurred occasionally, and chest, lumbar, and limb pains were sometimes noted. Diarrhœa was reported twice. In cases 23 and 30 there was transient mental confusion and excitement which may have been due to mild encephalitis; in the others the mind remained clear. Accentuated tendon-jerks were again noted in many patients, but the plantars were flexor in all cases except a child (case 35) seen at the end of November with a history of sudden headache following a period of malaise, and with mild meningitic signs and transient extensor plantar responses.

The others appeared during the same period as the encephalomeningitic cases just described, and the peak of incidence of the two groups fell within the same period (see figure). The chief features of these patients, who seemed to be less intensely affected by the same causal virus as was active in cases 1–22, are detailed in table II. The headaches were either predominantly or entirely frontal, and the fever tended to be irregular and intermittent. In nearly all cases temperatures of 102° to 103° F were recorded. In case 23 the spleen was just palpable for the first few days. As in the meningitic cases, there was in the blood a tendency to leucopenia and relative lymphocytosis rather than leucocytosis. The Widal and Paul-Bunnell tests were done in some of the cases and were negative in each instance.

Though in all cases the severe symptoms came on suddenly, there was in some of them a period of a few weeks in which there had been lassitude and subnormal health (cf. cases 8 and 17 in group I).

The diagnosis of "influenza" might have been applied to these cases had they not occurred in the same districts of N.W. Middlesex at the same time as the evident neurotropic-virus infections. That fewer of them were seen in hospital than the frankly encephalomeningitic types was probably due to the fact that other patients were not sufficiently ill to need hospital treatment. Cases 28, 30, and 34 were members of the Redhill Hospital nursing staff.

As in group I all the cases in group II made full and lasting recoveries.

CEREBROSPINAL FLUID FINDINGS

Table I shows that a great variety of results was obtained in the C.S.F. examinations, but not more than in other features. Some cases showed a very low cellularity, making them hardly separable from the "non-meningitic" cases. In cases 2 and 21 the cell-counts reached four figures. Usually our cases showed much fewer cells than did those detailed by Armstrong (1941). Polymorphs predominated at the outset in cases 3, 5, 14, 19, and 21, but in the other cases, though various numbers of polymorphs were seen early on, lymphocytes predominated.* In all cases where repeated observations were made the cells became increasingly lymphocytic as the illness took its course; and in the great majority no treatment, apart from the lumbar punctures, was used. The protein content was normal or only slightly increased in most cases, and its increase appeared to bear no constant relationship to the cell-count. The cases with high protein contents were the most severe in the series, and some of these showed very few cells. These cases may have been infected with a different virus from that in other cases. The protein showed no real tendency to rise, but was usually less in the later lumbar punctures. The chlorides, except for a fall in 1 case to 620 mg. per 100 c.cm., were little if at all reduced, and so support the view that they are a useful diagnostic aid in excluding tuberculous meningitis. On the other hand, cases of tuberculous meningitis may show a delay in the fall of chlorides, which causes a temporary difficulty in diagnosis.

The pressures recorded in the C.S.F. were extremely variable, and, allowance being made for the fact that in some of the small children the pressure was probably raised by nervous activity, there were a surprising number of low readings.

In all cases the fluid steadily returned towards normal in two or three weeks, but in several cases there was some excess of lymphocytes at the end of this time.

COURSE AND TREATMENT

The patients all made good recoveries, though 3 complained of occasional headaches for several weeks after discharge, and 2 with facial paralysis have yet to recover completely from these palsies. Most patients were in hospital two or three weeks; in the mildest cases the illness lasted about a week, but 3 of the patients most severely affected were ill six weeks. Case 8, with simple meningitic signs, showed a low fever for four weeks.

Treatment appeared to have little effect on the illness. Short courses of sulphonamides were given in cases 6, 15, and 20, but these patients did no better than many who had no treatment. Of 2 cases of equal severity, both treated with sulphonamides and penicillin, case 15 showed prolonged meningeal signs and case 20 showed rapid improvement. Other writers have not found sulphonamides effective in lymphocytic meningitis, but from our brief experience it is impossible to draw any conclusions about the effect of penicillin. There is rarely much need for special therapy, apart from the usual analgesic treatment for headaches.

Lumbar puncture gave symptomatic relief where the headache was associated with a raised C.S.F. pressure.

DISCUSSION

In 35 cases of infection, with headache and other features in common, seen in a large district during eight months, only rarely was there good evidence of the initial upper respiratory infection noted in benign lymphocytic choriomeningitis (Armstrong and Dickens 1935), but the illnesses were, in many cases, at first general and of sudden onset, the signs of nervous syst involvement following several days later. These nerv signs at times were well marked; at other times they v slight enough to be obscured by the general illness an make the clinician hesitate about lumbar puncture. spite of variable intensity of the illness and of the vari involvement of the nervous system, it is suggested t many of these cases were due to the same virus. is obviously impossible, without further examinati to say what that virus may be, but it may be no without any implications, that its effect on the nerv system resembles that of the virus of so-called "ben lymphocytic choriomeningitis" (Armstrong and Li 1934). *Our cases fall readily into Armstrong's* (19 purely descriptive classification of "influenzal," men gitic, and encephalomeningitic types (see also Armstr and Hornibrook 1941, and Keliher 1944). According Wyburn-Mason (1944), they also resemble cases infec with this virus in that most of them show a prodro premeningitic phase. A point of difference is the m incidence of our cases about midsummer (see figu whereas the group described by Armstrong occurr mainly in spring and autumn. Our cases also show much fewer cells in the C.S.F., on the average, than we found in his (Armstrong 1941). A further distincti between our cases and Armstrong's is the slender eviden in favour of a mouse-carried infection in the Middles cases (see below).

In looking for the source of the infection we have bor in mind Armstrong's (1940) report of the work of Lil and himself in which grey mice trapped at random w found to be harbouring the choriomeningitis virus. Th found also that mice caught in the homes of vir meningitis patients were very often infected with t virus.

Our inquiries on this subject gave various, but main negative, answers. Cases 3 and 6 came from hom "overrun with mice," and cases 4, 7, 9, and 19 had so mice in their homes. Yet case 14 had no mice at hom but had just spent a holiday in an old house in the countr In 22 cases, including 12 in group II, there were no mi in the homes. The houses in the district are for the mo part new; and many homes had cats, to which d tribute was paid.

In view of the prevalence of abortive influenza-li attacks in the past year, it is possible that some of the may be examples of a very mild type of neurotrop virus infection. Armstrong found considerable eviden of abortive choriomeningitis infection in the Unit States, where 11% of 2000 sera collected at random fro persons without history of nervous disorder contained an bodies for the virus. The possibility of such human agen in spreading these infections has yet to be fully exclude

Infections which may cause meningitic illnesses similar to those of our cases are mumps, glandular fever, Weil's disease, herpes zoster (Armstrong 1943), swineherds' disease (*Durand et al.* 1936), and pseudolymphocytic choriomeningitis (MacCallum et al. 1939). No evidence to support the first four conditions was found, and the fifth is mainly confined to France and Italy.

Though less similar, polioencephalomyelitis has to be considered in certain cases, such as 4 and 10, in our series, where the C.S.F. protein was raised and the cells little increased. In case 21 encephalitis lethargica has been considered as a possible cause of the illness; but it has been felt justifiable to include all three in the series. If their inclusion provokes disagreement, it is hoped that it may also serve as a reminder that in cases of this type the clinician greatly depends for an exact diagnosis on the help of the expert in virus infections.

---

* Since the end of this series two further cases of virus meningitis have been seen with well-marked initial polymorph predominance (80–90%) in total cerebrospinal fluid cell-counts of 300 per c.mm.

The virus of lymphocytic choriomeningitis (Armstrong and Lillie 1934) may cause a severe general infection and death, and Smadel et al. (1942) have described pneumonic lesions in two such cases. Though one of our cases had transient chest pain, we found no evidence of pneumonia in any of them, and so were unable to link the condition in any way with the virus pneumonias which have been prevalent in recent years, often with severe headache as a troublesome symptom.

In the group of cases described by Noone et al. (1936) one died of encephalitis, and another death was reported by Viets and Shields (1937). Whether due to the virus of Armstrong and Lillie or to a similar neurotropic infection, there is no need, at this point, to emphasise the fact that all these infections, though often transient, sometimes are not "benign" and are liable to be much more than a mere "choriomeningitis." The term "lymphocytic" also may not always be applicable in the early stages, if the Middlesex cases are to be taken as a guide; Wyburn-Mason (1944) also cites other authors who have noted a predominance of leucocytes in the early stages of virus meningitic infections.

In an attempt to isolate the causal agent, the following experiments have been carried out by Dr. F. O. MacCallum at the Central Public Health Laboratory, Colindale. Seven specimens of C.S.F. obtained on the sixth to tenth days from onset of illness, and nine specimens of blood obtained on the seventh to twentieth days from onset, were used for the inoculation of mice, guineapigs, white rats, cotton-rats, and rhesus monkeys. Three pools were used for mice and guineapigs, and one for rats, cotton-rats, and monkeys. The C.S.F. were inoculated intracerebrally, and blood and C.S.F. intraperitoneally. There has been no evidence of illness following inoculation of these animals. Examination of convalescent sera for antibodies for various neurotropic and other virus diseases will be done later.

CONCLUSION

It may be said that the weight of evidence is against these cases being due to an infection by the virus of Armstrong and Lillie. Whether one or more viruses were responsible for the infections also remains to be shown: and whereas it is easy to dismiss such a group of cases as due to various infections, it is more difficult to adduce certain evidence either for or against this conception. On the one hand, the well-known variations in the C.S.F. findings and the clinical picture, even in a recognised infection such as Armstrong's virus, and, on the other hand, the number of neurotropic viruses as yet not isolated, both make exact diagnoses difficult. An outbreak of virus infections of the nervous system, such as has been described from one district, always requires identification by an expert in virus diseases.

I am indebted to Dr. F. O. MacCallum and Dr. Robert Cruickshank, of the Central Public Health Laboratory, Colindale, for their help with the virus investigation of these patients; to Dr. J. Hamilton-Paterson and the Pathological Department at Redhill County Hospital for the other laboratory investigations; to my colleague, Dr. L. I. M. Castleden, for showing me three of the cases: and to Dr. F. Ashton for help with the investigation of the younger children.

CONTINUOUS INJECTION OF PENICILLIN

THE SECUNDERABAD APPARATUS

J. H. BOWIE
M.B. Edin.
MAJOR I.M.S.

M. D. BORCAR
CAPTAIN I.A.M.C.

G.H.Q. (INDIA) PENICILLIN RESEARCH TEAM

THE penicillin research team (India Command) was associated with the war wounds research centre at the India Command Orthopædic Hospital in Secunderabad, to which British troops were evacuated from Burma. The cases treated at the centre were mainly unhealed compound fractures of the femur. The average period between wounding and admission to the centre was three months, and in these cases penicillin often had to be administered over long periods. The general condition on admission was exceptionally low owing to the long-continued sepsis, malaria, dysentery, nutritional macrocytic anæmia, effects of heat, and other conditions inseparable from active service in this theatre.

The difficulties experienced in these cases, when penicillin was administered by three-hourly injections or by ordinary Army saline-giving sets, prompted the development of a method for continuous administration in small volume. In this we were encouraged by the results reported by the pioneers in continuous injection of penicillin (McAdam et al. 1944, Morgan et al. 1944) and by Army medical reports from Middle East and Europe by Brigadier J. S. K. Boyd, Lieut.-Colonel G. K. G. Mitchell, Major K. E. A. Hughes, and Major S. T. Cowan on their experiences with available methods of continuous injection. We concluded that penicillin should be injected continuously in as small a volume as possible, and that rubber tubing should be avoided. Since the amount of sodium penicillin commonly administered in twenty-four hours is readily soluble in 2 ml. of water, we formed the opinion that a syringe should be attached to the patient and some means evolved to depress the piston slowly over a period of hours.

Lieut.-Colonel H. R. Harley, who commanded the war wounds research centre, Captain R. A. Ree, R.E.M.E., and Lieutenant W. C. Osbourne, R.E.M.E., were associated with us in the development of the apparatus.

THE APPARATUS

The apparatus (fig. 1) consists of a 2 ml. syringe mounted on the convex surface of a small aluminium base plate: the syringe is retained in position by front and rear clasps. The concave surface of the plate is secured to the patient's skin with short 'Elastoplast' straps (fig. 2). Arranged on the base plate, behind and in line with the syringe, there is a lead-screw * which engages a screw-threaded hole in the centre of a sliding block (fig. 1). The block is supported by, and slides along, two guides which transfix the block and lie one on each side of, and parallel to, the lead-screw; these guides prevent rotation of the sliding block. The block is moved away from or towards the syringe by clockwise or anti-clockwise rotation of the lead-screw. The enlarged rear end of the piston rod is clasped in a suitable recess provided in the sliding block. The to-and-fro movement of the sliding block is communicated through a hollow piston rod to the piston block in the syringe barrel.

---

* A screw whose rotation causes an object threaded on to it to move to and fro along the axis of the screw: vices and adjustable spanners are examples of the principle.

The pitch of the thread cut in the lead-screw is such that twenty-four complete revolutions cause the piston to move up or down the syringe barrel a distance of 33 mm.; these excursions of the piston effect complete charge or discharge of the 2 ml. injection syringe.

To prevent clothes becoming caught up in the rotary mechanism, a transparent plastic removable cover (fig. 2) stretches from side to side over the lead-screw, syringe, and plate.

The lead-screw is rotated by an alternating-current electric motor acting through a flexible drive in the form of a motor-car speedometer cable in a flexible plastic sheath (fig. 2). The inner cable is attached to the lead-screw by inserting its square end into a square hole at the rear end of the lead-screw; the outer cover cable is attached to the base plate with a thumb-screw. Both inner and outer cables are therefore readily detachable. Each cable is 9 ft. long, and cables can be joined together lengthwise with simple junction pieces. Before the injection can start, sufficient torque must be built up in the inner cable; this occupies 5–7 min. for each 9-ft. length, attached lengthwise between motor and syringe, at the slow speed of rotation by the specially low-geared motor.

Between the motor and the flexible drive cable a reduction gearing system is interposed to produce twenty-four revolutions in twenty-four hours in the lead-screw on the base plate; it thus takes a day to evacuate the syringe.

To cope with fluctuations in voltage, a centrifugal constant-speed device is incorporated between the motor and the reduction gearing system.

To recharge the syringe, rotation of the flexible drive is performed by hand with a gramophone winding handle, after disconnecting the reduction gearing and motor from the flexible drive with a clutch.

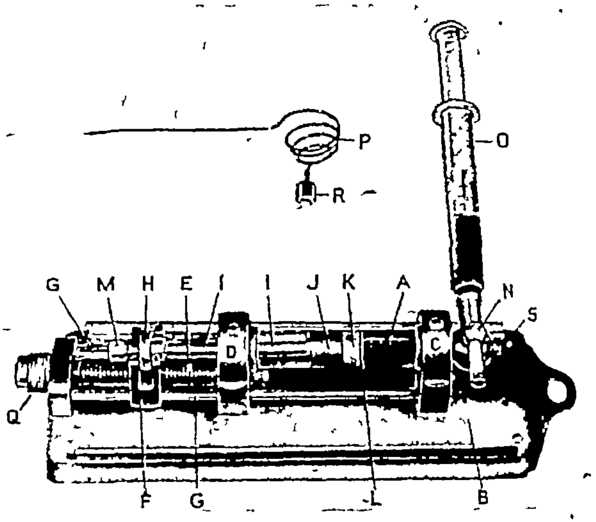

Fig. 1—Base plate and injection syringe (with needle and flexible drive detached) to show details of lead-screw and loading syringe in position: A, injection syringe; B, base plate; C and D, front and rear clasps; E, lead-screw; F, sliding block; G, sliding block guides; H, enlarged rear end of piston rod; I, hollow piston rod; J, piston block; K, ring of resilient material; L, circular disk; M, regulating thumb-screw to adjust K; N, three-way tap; O, reloading syringe; P, flexible coiled injection needle; Q, thread to attach thumb-screw of flexible drive outer cable; R, needle-retaining nut; S, thread for R.

Owing to the slow advance of the piston during injection of 2 ml. in twenty-four hours the liquid in the syringe tends to leak past the piston. To obviate leakage at this point the piston is fitted with a ring of resilient material disposed between a shoulder at the front of the piston block and a circular disk, the diameter of which is a shade less than the bore of the syringe (fig. 1). The position of the disk is controlled with a rod fixed to its rear flat surface. The rod extends axially of the piston rod, which is tubular, and is provided at its free end with a regulating thumb-screw. By moving the disk towards the shoulder with the thumb-screw, the ring of resilient material is expanded in diameter and can thus be brought into very close engagement with the interior of the syringe barrel and in this way prevents any leakage past the piston. The regulating thumb-screw can be adjusted while the piston is in motion.

The end of the syringe to which the needle is not attached is closed with a small pledget of wool inserted between the inner surface of the barrel and the piston rod; this maintains sterility inside the syringe during the daily excursions of the piston. The wool is kept in position with a cap which fits over the syringe barrel and is enclosed by the rear clasp retaining the syringe on the plate.

The end of the syringe to which the needle is attached is provided with two exit openings controlled with a three-way tap (fig. 1). One of the openings forms an adapter for the nozzle of a second syringe, with which the injection syringe can be automatically recharged by twenty-four manual rotations of the lead-screw through the flexible drive. This adapter is flamed before reloading, and sterility is maintained during the twenty-four-hour injection period with an air-tight cap.

The second exit opening from the injection syringe forms the

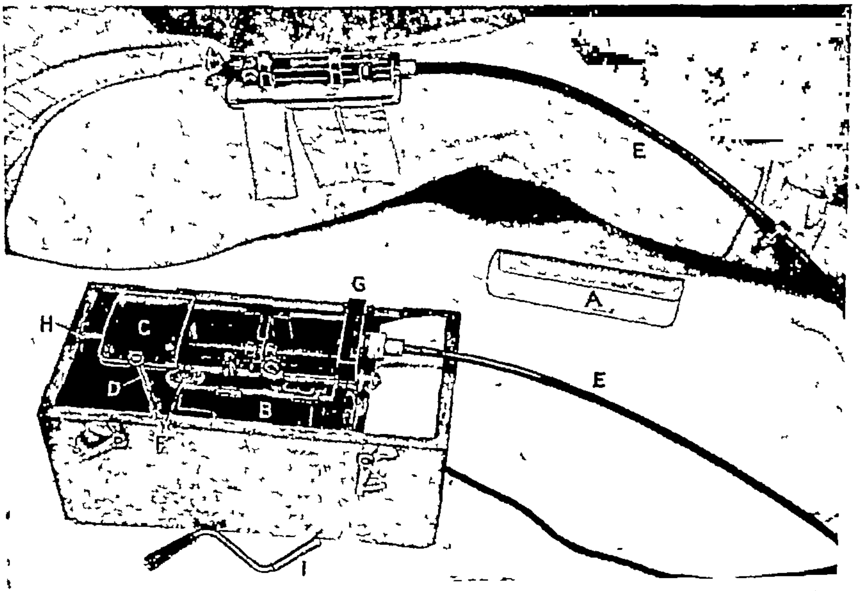

Fig. 2—Apparatus set up for use on patient: A, plastic cover to protect syringe and coiled needle; B, motor; C, reduction gear-box; D, clutch handle; E, flexible drive (speedometer cable); F, tripswitch; G, distribution box; H, spindle for reloading; I, handle for reloading.

concavity into which the bulbous end of the special injection needle is clamped with a retaining nut; the method is similar to the fixation mechanism between needle and syringe in the type of all-metal syringes used to induce local anæsthesia in dentistry.

An intermediate portion of the needle is coiled like a delicate spring (fig. 1) to impart flexibility to the needle; the coil takes the place of rubber or plastic tubing in other methods of continuous injection. The needle can be suitably shaped for intramuscular, subcutaneous, or intravenous injection.

ADVANTAGES

This method has the following advantages over other methods described for continuous injection:

(1) The mechanical advantage inherent in rotary drive through a lead-screw ensures an absolutely constant injection; this in turn ensures a maximal constant blood-penicillin level at minimal expenditure of the drug.

(2) The mechanism of the sliding block is identical with that of an ordinary vice, and the potential pressure under which the injection is effected is 52 lb. to the square inch; this eliminates the possibility of blockage in the needle during injection.

(3) Supervision is unnecessary, except when the apparatus is set up on the patient and when the syringe is recharged at intervals of twenty-four hours. The penicillin produced by most manufacturers causes some tissue damage at the site of continuous injection; this is rendered apparent on the fourth or fifth day by the onset of tenderness near the needle. It is advisable to avoid the possibility of abscess formation by changing the site of the needle every four or five days.

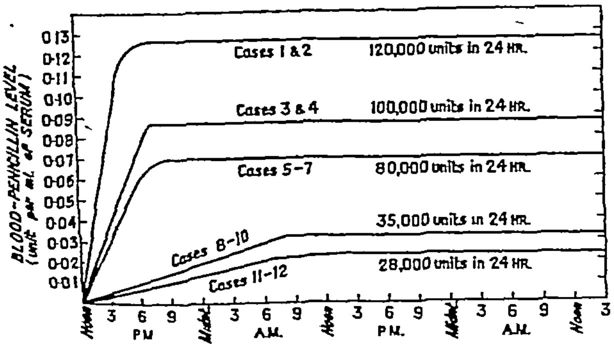

Fig. 3—Average blood-penicillin levels in patients on same doses, assayed three-hourly and adjusted for a standard body-weight of 140 lb.

(4) The small volume (2 ml.) in which the penicillin is injected reduces proportionately (*a*) pain and local œdema, and (*b*) deterioration of the penicillin at room temperature.

(5) The patient is not confined to bed but to the length of his cable. He can sit at the bedside and, since the flexible cable drive is attached to the syringe base plate with a thumb-screw, he can leave the ward by separating the cable at this point.

TABLE I—CONSTANT BLOOD-PENICILLIN LEVELS UNDER CONTINUOUS ADMINISTRATION OF PENICILLIN

Case no.	Body-weight (lb.)	Daily dose of penicillin (units)	Constant blood-penicillin level attained within 48 hr.	Figures in previous column corrected for standard body-weight of 140 lb.	Dose, calculated from daily dose and blood-penicillin level, required to maintain a constant level of 0·02 unit of penicillin per ml. of serum per 140 lb. of body-weight
1	142	120,000	0·128	0·13	18,500
2	135	120,000	0·128	0·123	19,500
3	180	100,000	0·068	0·087	23,000
4	175	100,000	0·068	0·085	23,500
5	138	80,000	0·068	0·067	24,000
6	160	80,000	0·068	0·077	20,500
7	136	80,000	0·068	0·066	24,000
8	136	35,000	0·032	0·032	22,500
9	170	35,000	0·023	0·028	25,000
10	140	35,000	0·032	0·032	22,000
11	140	28,000	0·023	0·023	25,000
12	134	28,000	0·023	0·022	25,500
13	132	28,000	0·023	0·022	26,000

(6) Booster doses can be given at any time during treatment—e.g., in the operating theatre—by manual rotation of the flexible drive.

(7) According to the number of cable adapters fitted to the distribution box on the motor, any number of patients in a ward can be treated simultaneously.

(8) The penicillin is not in contact with rubber tubing, which may have a deleterious action on it. Soft flexible tubing of any sort entails dead space and limitation of movement on the part of the patient in avoiding kinks.

BLOOD-LEVELS OBTAINED

Assays of penicillin were performed at short intervals on the serum of patients under continuous administration with this apparatus, to determine whether the blood-penicillin level was constant or rose during the night, and whether it varied among individuals on the same dose.

The blood-penicillin level was assayed by a slide-cell test based on that of Colebrook et al. (1923), as modified by Florey and Florey (1943), Heatley (1944), and Fleming (1943 and 1944).

Since it was desirable that abnormal blood volumes should not distort results, and since blood would have to be taken at short intervals during the day and night, we used volunteers among convalescent patients.

Two patients were put on 120,000 units per twenty-four hours, two on 100,000, three on 80,000, three on 35,000, and three on 28,000. The penicillin used was 'Lederle' no. 782 H134C, expiry date Sept. 23, 1945.

The constant blood-penicillin level attained in each case is given in table I, with the patient's weight and the

TABLE II—CALCULATION OF BLOOD-PENICILLIN LEVEL FROM BACTERIOSTATIC LEVEL

Bacteriostatic level (completely bacteriostatic dilution indicated by the sign –)								Amount of penicillin present per ml. of serum	
1/1	2/3	1/2	1/3	1/4	1/6	1/8	1/12	When the sensitivity of the test organism in serum is between 0·016 and 0·02 unit per ml.	When the sensitivity of the test organism in serum is between 0·02 and 0·033 unit per ml.

dose, calculated by proportion, which would have been necessary, in twenty-four hours, to maintain a level of 0·02 unit of penicillin per ml. of serum at a body-weight of 140 lb.

The values obtained from the three-hourly test results in patients on the same dose were combined after adjusting for a standard body-weight of 140 lb., and the resultant blood-penicillin curves are shown in fig. 3.

In view of the small number of patients and the range of experimental error in the slide-cell test, the results shown in table I and fig. 3 indicate that, in patients under continuous injection of penicillin, the blood-penicillin level becomes constant after a "building-up" period, does not vary appreciably in different individuals on the same dose, and is directly proportional to the dose and inversely proportional to the weight.

TECHNIQUE OF SLIDE-CELL TEST

Before giving penicillin we obtained sufficient serum from the patient for use, undiluted, as the diluent in the serial doubling dilutions of all assays to be performed in his case. The test was performed only once a day—not immediately the specimen was taken. The sensitivity of the test organism (N.C.T.C. 6571 A) was determined daily.

From each patient, *at three-hour intervals for forty-eight hours*, 0·5-ml. samples of blood were collected in capillary tubes made from lengths of glass tubing (3 mm. internal diameter) drawn off and sealed at both ends in lengths suitable for centrifuging. The tubes were stored vertically at 4° C until centrifuged immediately before the test; we could detect no reduction in the penicillin content of specimens stored in this way up to thirty hours. The specimen was well mixed, and immediately afterwards volumes of 25 c.mm. were removed with a micropipette and placed clockwise round 6-in. petri dishes selected for flat surfaces on the inner aspect of bottoms and lids. A 3 : 2 and then doubling dilution series were interpolated between dilutions in the 1 : 2 series.

The inoculum consisted of a 2 mm. loopful from a well-shaken suspension of the test organism, prepared just before the test, by inoculating 10 ml. of nutrient broth of pH 7·4 with two loopfuls from a well-shaken 10-ml. 16–18-hour broth culture of the test organism which had not been subcultured in broth more than eight times. The strain was maintained on nutrient agar slopes of pH 7·4 and subcultured once a week.

Since we desired to express the highest completely bacteriostatic dilution of the serum in terms of the number of units of penicillin per ml., it was necessary to know the sensitivity of the test organism; this varied between 0·016 and 0·033 unit per ml. in undiluted serum. A slide cell sensitivity test in triplicate, using P.B.S. in serum in the dilutions 0·08, 0·04, 0·033, 0·02, 0·016, 0·01, and 0·008 unit per ml., was therefore put up in parallel with each day's test.

The highest dilution of the test serum showing complete bacteriostasis having been determined, the equivalent in terms of units of penicillin per ml. of serum was expressed from table II, compiled for the purpose.

ESTIMATION OF DOSAGE REQUIRED

The dose of penicillin required for any particular patient may be estimated if the resistance of the invading pathogen and the patient's body-weight are known.

The blood-penicillin levels described above indicate that a dose of 25,000 units will maintain a blood-penicillin level of 0·02 unit per ml. for every 140 lb. of body-weight. From this datum the dose required to obtain the required blood-penicillin level in any particular patient can be calculated easily by proportion. For instance, if the organism is sensitive to 0·16 unit of penicillin per ml. (eight times more resistant than the Oxford staphylococcus) in a patient with endocarditis whose weight is 7 st., a booster dose of 10,000 units followed by a 24-hour maintenance dose of 140,000 units given continuously would be required.

SUMMARY

The development of an apparatus with which penicillin can be injected continuously in a very small volume of diluent was prompted by the disadvantages, mainly from the patient's point of view, of the methods used for continuous injection, especially over a long period. At the same time some difficulties, such as needle blockage and those associated with connecting tubing of any sort, have been avoided.

Blood-penicillin levels, observed in a few patients under continuous injection, indicate that the level becomes constant throughout the day and night after a "building-up" period and is directly proportional to the dose and inversely proportional to the patient's weight.

For every 0·02 unit of penicillin per ml. required in the serum, a dose of 25,000 units a day per 140 lb. of body-weight must be given.

The apparatus might be used in research on the action of other drugs.

Lieut.-Colonel A. Sachs, assistant director of pathology, India Command, suggests that, if high blood-penicillin levels were required at intermittent periods, such as those resulting from three-hourly injections of 15,000 units, a suitable gear wheel to effect this could be included in the reduction gearing system.

An application for a patent, together with a provisional specification, has been lodged at the Patent Office, and all patent rights have been assigned to the Ministry of Supply.

The apparatus is being made by Surgical Equipment Supplies Ltd., Westfields Road, N. Acton, London, W.3, to whom the Ministry of Supply have granted an exclusive licence to manufacture without payment of royalties.

We have pleasure in acknowledging the help of Brigadier F. Harris, Brigadier G. K. Fulton, and Colonel E. H. Hall, who formed and equipped the team and later directed the work. Special facilities were extended to the R.E.M.E. officers wit whom we worked by Major-General D. R. Duguid, who too an active interest in our problems. For their coöperation w wish to thank Colonel D. C. M. Ettles, who commanded th hospital to which we were attached; Lieut.-Colonel J. S Maxwell, in charge of surgical division; and Nursing Officer D. Eales, of the war wounds research centre.

The photographs were taken by Mr. E. V. Willmott, A.R.P.S. in charge of the photographic department, British Postgraduate Medical School.

MAMMARY CYSTS

AND THEIR TREATMENT

F. C. Pybus
M.S. Durh., F.R.C.S.

CONSULTING SURGEON, ROYAL VICTORIA INFIRMARY, NEW CASTLE-UPON-TYNE; EMERITUS PROFESSOR OF SURGERY IN THE UNIVERSITY OF DURHAM

A FAVOURABLE experience in treating hydrocele of th tunica vaginalis and cysts of the epididymis by aspiratio and injection of quinine and urethane[1] led to trial of thi treatment in 1934 for a mammary cyst in a patient wh had previously had two removed at some years' interval Its success justified its use in 2 further cases early i 1935, the successful results of which have been pub lished.[2] A further experience of 21 cases dealt with b this method has suggested a more detailed and complet report.

Incidence

The "single" cyst, as its name suggests, may be th only mammary lesion during a lifetime. There ar exceptions, however: a further cyst may develop month or years afterwards, or a cyst may develop simultaneousl or subsequently in the other breast. Thus the conditio is essentially different from those rarer lesions wher multiple cysts are present, and from those associated with papillomata. It is a condition of middle age and is about equally divided between the parous and non-parous. Observation of some patients for twelve years shows that the breasts may remain otherwise normal. The presence of a single cyst therefore does not suggest the existence or necessary development of any serious disease.

---

[1] Pybus, F. C. *Brit. med. J.* 1930, i, 239.
[2] Pybus, F. C. *Lancet*, 1936, ii, 853.

The *contents* of such cysts are almost invariably a turbid greyish-green fluid, which leaves a brownish stain on linen. The contents of some of them have been investigated chemically by Dr. Freda Herbert, who reports that they contain mainly cholesterol, phospholipins, and a variable amount of protein but no sign of hæmoglobin or its derivatives. The amount varied from 1 to 30 c.cm., with an average of 5 to 10 c.cm. It is suggested that the contents are a liquefaction of the greyish-green greasy material which occupies the ducts of many breasts in middle age.

From a study of a table of *symptoms* it appears that about half the patients discover the lump accidentally, and the other half had pain or discomfort lasting from a few days to months.

The *physical signs* are, as might be expected, very variable. This depends partly on the size of the breast, the size of the cyst, and its situation in relation to depth and whether placed centrally or radially. Thus in a small breast a moderate-sized cyst may be visible or readily palpable as a tense, rounded, or oval swelling which appears to move about within the breast tissue but actually moves with the breast substance. In larger breasts the cyst tends to be less readily defined; and, if placed centrally, it may closely resemble a scirrhus—a central hard ill-defined lump, except for the absence of signs of infiltration or gland metastasis. In many cases the cyst closely resembles a fibro-adenoma (an uncommon tumour) and can be distinguished only by puncture.

It is only occasionally that fluctuation can be obtained, depending on size, absence of undue tension, a superficial position of the cyst, or a dome-like projection on the surface. A suitable apparatus for transillumination has not been available. Final confirmation can be obtained by *puncture*, when the loss of resistance of the needle on entering the cyst is characteristic and the usual fluid appears in the syringe.

Treatment

After aspiration of the contents, 1 or 2 c.cm. of quinine and urethane (*B.P.C.*) is injected. No pain is felt and there is an absence of discomfort or inflammation. No dressing or bandage is used, the cavity remaining obliterated by atmospheric pressure.

After the original report,[2] it was felt that aspiration alone might cure: 3 patients were dealt with in this way, and in each case the cyst filled within three months. Subsequent aspiration and injection have led to cure.

Results

Of the 24 patients treated all have remained free from recurrence for 1–12 years. In 3 cases a cyst developed in the other breast, and was dealt with in the usual way.

A further case was missed and operated on under the impression that it was an adenoma, while in 2 other cases puncture was done on lumps resembling cysts, one a chronic abscess and the other a small hard oval scirrhus.

SUMMARY

The mammary cyst can generally be recognised from the symptoms and physical signs, but puncture should be used more often as a diagnostic method.

Aspiration followed by injection of quinine and urethane can cure such cysts, saving unnecessary operations.

Knowledge that some 25% of "breast lumps" may be cured by this means may reduce the reluctance of women to seek timely advice.

SCRUB-TYPHUS VACCINE

FIELD TRIAL IN SOUTH-EAST ASIA

W. I. CARD
M.D. Lond., F.R.C.P.
PHYSICIAN TO OUTPATIENTS, ST. THOMAS'S HOSPITAL, LONDON
LATE LIEUT.-COLONEL R.A.M.C.

J. M. WALKER
M.A., B.M., B.Sc. Oxfd
LATE MAJOR R.A.M.C.

WITH the early realisation in 1943 that scrub-typhus would form a major medical problem in operations in South-East Asia, all measures likely to combat it were reviewed, and as a result work was started at the National Institute for Medical Research on the production of a vaccine. This experimental work proceeded with such vigour that the first small consignment of cotton-rat-lung vaccine arrived in Delhi in November, 1944. The experimental work leading to its preparation has been described by Fulton and Joyner (1945), and Buckland et al. (1945). This vaccine had been shown to protect laboratory animals, and it was decided, in view of the urgent need, to press for large-scale production forthwith, without waiting for the results of field trials.

Early in 1945 attempts were made to organise field trials in North Burma with the earlier experimental batches. Our rapid advance in Burma, however, followed by the withdrawal of the Fourteenth Army to India to prepare for the next phase of the campaign, frustrated these attempts.

A fresh start was made in July, 1945, on troops of a selected corps of the new Fourteenth Army, but the Japanese surrender before these left India diminished the likelihood of any adequate field trial for the following reasons:

(1) In the absence of jungle fighting, the risk of infection would be greatly reduced. An army of occupation living under relatively static conditions is rarely in close or protracted contact with the terrain associated with scrub-typhus.

(2) The use of dibutyl phthalate (D.B.P.), or other mite-repellent, as borne out by the experience of the Australian and American armies, profoundly diminishes the attack-rate of scrub-typhus. Repellants were now being energetically employed in South-East Asia.

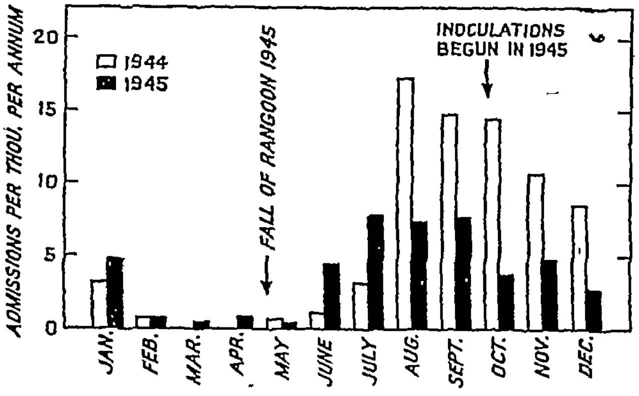
(3) The main criterion of the value of the vaccine must lie in its effect on mortality. In the Allied land forces in South-East Asia (ALFSEA) and the Pacific area, the case-mortality rate was about 10%; but this mortality had only occurred in troops exhausted by battle and where early treatment was difficult to obtain. Where fresh troops doing jungle training with immediate access to hospitals were attacked—e.g., in the Ceylon outbreak in 1943, and in the jungle training school in Mysore—the case-mortality was only 2%. If this were to be the figure in the army of occupation, many hundreds of cases in the inoculated and uninoculated groups would be required to provide significant data. Owing to the conditions stated above it was very doubtful if sufficient numbers of cases would arise.

This pessimistic forecast of the proposed field trial was ultimately justified by events, but it was felt that every effort at evaluation of this vaccine should be made.

METHOD OF INVESTIGATION

By this time (September, 1945) vaccine was arriving in fair amounts, and it was decided to distribute it to 10,000 troops on a controlled basis, while the remainder was allotted to Burma Command, where uncontrolled inoculation of those troops most exposed to risk was carried out.

The original plan for controlled inoculation provided that for every man receiving the vaccine there should be a control exposed to the same risk, in view of the pin-point distribution of infected areas and possible variations in strain virulence. The size of the groups should be, so far as possible, a section of 10 men. It should be made clear that controlled inoculation was perfectly justifiable, since there was insufficient vaccine for every man. Avail-



Incidence of scrub-typhus in Burma.

able vaccine was never withheld. This ideal plan had to be modified in practice since commanding officers, aware of the vaccine, expected it to be given to all troops at risk. A compromise course was usually adopted, two-thirds of the unit being vaccinated, leaving a third—normally the H.Q. troops—as controls. The units chosen were those considered to be most at risk—i.e., engineer companies engaged in bridge-building and jungle clearance, drainage, &c., and infantry units engaged in patrolling, surrounding, and searching villages. In all, between July, 1945, and February, 1946, sufficient vaccine was distributed for the vaccination of over 60,000 men, though only 10,000 of these were inoculated on a controlled basis.

As recommended by the Medical Research Council, 1 c.cm. of vaccine was given on three occasions at weekly intervals. No reactions were observed, and troops were always fit for arduous training next day.

The use of D.B.P. or other mite-repellent was not withheld where it was available to units. The men had been drilled in its use in the Burma campaign; it was not considered justifiable to forbid it after the Japanese surrender.

The plan for the follow-up of cases of scrub-typhus included a special proforma distributed to all medical formations to be forwarded on completion to the director of medical services, ALFSEA. This proforma carried a list of those symptoms and signs whose presence would enable the severity of the attacks to be estimated.

RESULTS

In South-East Asia, in the period under consideration, 33 cases of scrub-typhus developed in inoculated persons. Of these, 2 were infections in research-workers in the scrub-typhus research laboratory, ALFSEA, and 31 were in troops. Of these 31 troops, 7 had received the full course of three inoculations. The remaining 24 had begun the course while actually incubating scrub-typhus, and the onset of the disease had prevented their receiving more than one or two doses.

It was thought that the effect of the vaccine might possibly be demonstrated by one or more of the following results:

(1) A modified clinical course in inoculated persons.

(2) Changes in the serological reactions during the course of the disease.

(3) A fall in mortality-rate in inoculated persons.

(4) A lowered incidence among inoculated persons.

Clinical Course in Inoculated Persons.—There were 9 cases of scrub-typhus in fully protected persons: 2 of them in research-workers, and 7 in troops. Of these 9 patients 7 had mild attacks, 1 had a severe attack, and 1 was very severely ill and nearly died. In 4 of them the duration of fever was less than fourteen days, and in 5 of them fourteen days or more. These cases gave no indication that inoculation with the vaccine had any pronounced effect on the duration, severity, or complications of the disease.

Van den Ende et al. (1946) have described 4 cases of scrub-typhus in immunised research-workers. All the patients were severely ill, and there was little modification of the disease. The patients in South-East Asia, however, were infected by mites, whereas the cases reported by van den Ende were due to accidental infection in the laboratory and may therefore have received relatively enormous infections.

Serological Reactions during the Disease in Inoculated Patients.—A study of the case-records does not reveal any great difference in the serological reactions of the second and third weeks between inoculated and uninoculated patients.

Effect of Vaccine on Case-mortality.—The period covered by the field trial was from July, 1945, to January, 1946, inclusive. During this period the case-mortality rate in unprotected troops was 3%, whereas no deaths took place among the 33 protected persons who contracted scrub-typhus. To show that this fall in case-mortality from 3% to nil was significant, it would be necessary to obtain a series of about 200 cases in inoculated persons without a death. From this evidence, therefore, no conclusion can be drawn about the effect of the vaccine on the mortality.

Effect of Vaccine on Incidence of Scrub-typhus.—Controlled inoculation had been carried out on two divisions, and it was thought that the incidence in inoculated troops might prove to be significantly lower than that in the controls. But in the areas occupied b these two divisions scrub-typhus was much less commo than was expected, only 6 cases and 3 cases arising durin the period from October, 1945, to January, 1946 inclusive; the effect of the vaccine cannot therefore b assessed.

In Burma, however, the overall incidence of scru typhus remained fairly high. The admission-rate fo 1944 and 1945 is shown in the figure. This shows th well-marked seasonal variation and the reduced incidenc in 1945. This reduction was probably due to the us of D.B.P., which was started in December, 1944, and t the cessation of fighting after the capture of Rangoo in May, 1945.

CONCLUSIONS

An attempt to assess the value of the vaccine from th admission-rates in Burma leads to the following conclu sions. In November and December, 1945, and January 1946, there were 7 cases of scrub-typhus in persons wh had received a full course of three inoculations. Sinc the average number of fully protected troops in Burm during this period was about 15,000, this is an incidenc of 1·8 per thousand per annum. The incidence i unprotected troops over the same period was 3·1. Th difference is not statistically significant.

The failure of the field trial to produce conclusiv results is due to the low incidence of scrub-typhus i South-East Asia since July, 1945. The predominantl static rôle of our troops since that date was partl responsible for this low incidence. But a large part o the credit must go to unit commanding officers; wh have throughout keenly appreciated the danger of scrub typhus and have shown their determination to preven it by insisting on the regular use of D.B.P. and protectiv clothing by their men.

SUMMARY

A field trial of scrub-typhus vaccine is described.

There were 9 cases of scrub-typhus in fully protecte persons, and 24 in partially protected persons.

It is impossible, on the limited evidence, to say whethe or not the vaccine has any effect on the mortality o incidence of the disease.

The available evidence suggests that the vaccine has no well-marked effect on the clinical course or serological reactions of scrub-typhus.

We wish to thank Lieut.-Colonel M. H. P. Sayers, R.A.M.C., assistant director of pathology at the War Office, for his help throughout the work; and the Director-General, Army Medical Services, for permission to publish this paper.

EPILEPSY AND HYSTERIA

D. N. PARFITT
M.D. Lond., B.Sc. Wales, M.R.C.P., D.P.M.
LATE WING-COMMANDER R.A.F.; NEUROPSYCHIATRIC SPECIALIST; MEDICAL SUPERINTENDENT, HOLLOWAY SANATORIUM, VIRGINIA WATER

THE differentiation of hysteria from epilepsy is a not unusual problem in peace-time. In war-time it arises even more often, because the epilepsy commonly met with in the Services is milder, and because strong desires to stay in or leave the Services affect the patient's description of his symptoms.

When undoubted epileptic phenomena develop, an electro-encephalogram (E.E.G.) is unnecessary, although Wassermann and other tests may be imperative. The first of the two purposes of this brief note is to emphasise that, when doubtful epileptic manifestations develop in the presence of an acceptable psychological setting and in the absence of organic changes, it is still wise to have an E.E.G., for an organic factor may be revealed, and it is well to take every precaution against mistakes in diagnosis.

In the problem cases considered here I have found the psychiatrist's reliance on psychological mechanisms more prone to be false than the neurologist's insistence on pathology. This is because hysterical symptoms often grow from an organic nidus, congenital or acquired, under the influence of psychological fertilisation. Brain lesions predispose to psychogenic symptoms referable to the brain, and a liability to occasional or frequent epileptic phenomena may be accompanied by hysterical amplification in any proportion. The difference between the two is sometimes denied and hysteria regarded as "psychic" epilepsy (Lennox 1941).

A family or personal history of neurotic traits and an intelligence less than average are common in epilepsy and hysteria. Emotion, fatigue, the menstrual cycle, and alcohol can precipitate attacks of one or the other. I have seen several youths whose epilepsy has become manifest after heavy drinking on leaving home for military service. The fluid intake may be the important factor here, however. Minor physical signs are uncommon in both epilepsy and hysteria, and although diminished or lost reflexes or slight differences on the two sides, spastic eye movements, and so on, are more often met in epilepsy they are not conclusive. A passive reliance on the doctor's opinion favours epilepsy, as does a keenness to continue service in military cases, accompanied by pleading rather than a protest, but these points are not pathognomonic. In over 50% of doubtful cases there was no history of relevant symptoms before service. The age of onset in the epileptics was 21–38 years and averaged 29 years.

Rosenberg (1943) has decried the value of the E.E.G. in circumstances of doubt, but one feels he asks too much. A report on an E.E.G. may say that there is "no evidence of ——," "a possibility of ——," "support for ——," or "typical of ——," epilepsy. With the last three it is wiser to accept an organic factor. "No evidence ——" leaves one's opinion as before.

CASE-RECORDS

Case 1.—Man, aged 40, mental age 13 (normal 14). Unhappy in the Service. His wife and son had tuberculosis, and separation was distressing. Was bitter in the belief that boys half his age, of less ability, were promoted over his head. Complained of attacks of unconsciousness lasting 30 min.; no injuries, no incontinence, no twitching. His mother was highly strung and had similar faints under the influence of emotion. After his turns he trembled violently. He had often stopped attacks by "will-power." Yearly attacks began at 16, but the last three had been at two-month intervals. No medical or Service confirmation. The E.E.G. report was: "Typical, with bursts of fast activity quite characteristic of grand mal epilepsy."

Case 2.—Man, aged 21. He had his first attack at 14 when he saw his younger sister run over and killed by a lorry. Seven attacks followed in the next 4 years, but the succeeding 3 years were clear. On one occasion he fell and sustained mild concussion. The attacks began with tingling and numbness which started in the left foot and spread up the limb. When they reached the top of the thigh the patient fainted. He could stop attacks when walking by a tremendous effort of will, and when sitting by putting his head between his knees; but he then saw double and trembled. Attacks came on during drug therapy, and he was finally relieved, before service, by psychotherapy and hypnotism. He was a prospective member of aircrew and had recently had another attack. The E.E.G. findings of Dr. Denis Williams supported the diagnosis of epilepsy.

The second purpose of this report is to serve as a reminder of the type of case which might be dismissed as a migrainous headache, where there is nausea and sometimes a tendency to "blackout" with the pain. There were 4 such men among 20 "problem" cases, the diagnosis lying between migraine, epilepsy, and hysteria.

Case 3.—Man, aged 21. Over the last 6 months he had had severe one-sided headaches accompanied by nausea lasting up to 3 hours, brought on by wearing a steel helmet. He lost his ability to concentrate on his work, became giddy, and saw spots before his eyes. He felt himself stopping and staring for no reason and was listless after the attacks. The E.E.G. report was "Possibility of epilepsy."

It is advisable not to enlist epileptics. When they are already serving, especially if trained for work involving no danger, it is often possible to retain them, and more than half the epileptics I have seen have been so retained. Their work must not be dangerous.

The diagnosis between epilepsy and hysteria is sometimes impossible, and further evidence must be awaited. Anticonvulsive drugs are better avoided in doubtful cases.

CONCLUSION

Hysterical and migrainous symptoms are sometimes embellishments of epilepsy. An electro-encephalogram in such cases is often valuable but may not be conclusive.

"... The other new decision is to set aside twenty State scholarships for older students who have missed a university education but have shown their qualification for one in later life. It is a small beginning, but much can be expected from it, and the provision of scholarships in this adult field should be rapidly increased. In all universities at present the merit of the ex-Service students, who are in so great a majority, is recognised as outstanding. They are resolute in study, and their responsiveness, their ready intellectual grasp, delights their teachers. No greater proof is needed of the wisdom of enabling men and women of mature mind and wide experience of life to attend the universities."—*Times*, March 28.

Preliminary Communication

MODIFICATION OF HUMAN RED CELLS BY VIRUS ACTION

AGGLUTINATION BY "INCOMPLETE" RH ANTIBODY

BOTH the virus-hæmagglutination phenomenon and the "incomplete" Rh antibodies have lately received the attention of several workers.

Burnet et al.[1] have shown that the treatment of human red cells with cholera filtrate removed the receptors on the cells for the influenza group of viruses. Pickles[2] has shown that Rh-positive cells sensitised with "incomplete" Rh antibodies were agglutinated when cholera filtrate was added. Agglutination also took place when Rh-positive cells, previously treated with cholera filtrate, were exposed to a serum containing the "incomplete" Rh antibody and from which the panagglutinin had previously been absorbed.

In a few preliminary experiments we have confirmed the observations of these workers. It occurred to us that several points of analogy existed between the influenza group of viruses and the cholera-filtrate factor, *in so far as their actions on red cells* were concerned. Our experiments show that the treatment of Rh-positive cells with certain viruses modifies the cells so that they may be agglutinated by the "incomplete" anti-D Rh antibody.

MATERIALS AND METHODS

Four viruses were used: influenza A, PR 8 strain; influenza B, Lee strain; swine influenza, Shope; and Newcastle disease virus, Doyle's strain (N.D.V.).

The viruses were grown in the allantoic sac of ten-day-old chick embryos. For each virus the allantoic fluid from six eggs was collected 48 hours after inoculation and pooled. The virus titre[*] of each was determined by hæmagglutination tests against human and fowl red cells, and the identity of each virus was checked by hæmagglutinin inhibition tests with specific immune sera.

All preparations were bacteriologically sterile, kept at 4° C, and used within three weeks after collection.

The virus treatment of the human Rh-positive and Rh-negative red cells was carried out as follows:

To 0·25 c.cm. of virus-infected allantoic fluid was add an equal quantity of a 2% suspension of washed hum red cells. The tubes were kept at 4° C for $^1/_2$–1 hour, b which time the cells were agglutinated by the virus and h completely settled out. The tubes were then placed in 37° C water-bath, with periodic shaking, for two hou In this way the viruses were eluted from the red cells, whi then became more or less stable in suspension. The treat cells were then centrifuged down and, after the supernata fluid had been removed, washed once in saline and resuspend in saline to 2% strength. Cells similarly treated with sali were included as controls.

The agglutination of these virus-treated cells by a "incomplete" Rh antibody was carried out with th use of a serum diluted 1/32 which contained the "incom plete" form of the anti-D Rh antibody to a titre *1/256 and from which the anti-A and anti-B* is agglutinins had been absorbed. A normal human serum was used as control. The tests were incubated at 37° until the cells had settled to the bottom of the tube and the results were read macroscopically and microscopically.

Cells treated with N.D.V. and influenza B were usually completely stable after elution. Those treated with influenza A and swine influenza were usually only moderately stable. This, however, did not interfere with the readings, as virus-agglutinated cells were very

readily redispersed when gently pipetted and spread on a 3 in.×1 in. microscopical slide, with the result that they appeared unagglutinated when examined microscopically. Treated cells sensitised with the "incomplete" Rh antibody showed definite agglutinated clumps macroscopically and under the microscope.

Twenty-four specimens of human red cells, including 16 Rh-positive and 8 Rh-negative, have been examined so far. The results of the tests are shown in the accompanying table.

RESULTS

The strongest and most clear-cut results were obtained with the N.D.V.-treated cells. Only the Rh-positive treated cells which contain the D Rh antigen were agglutinated by the "incomplete" anti-D Rh antibody. Treated Rh-negative cells, which do not contain the D Rh antigen, were not agglutinated. With the other viruses the reactions were weaker and more irregular, variations in the susceptibility of the individual cells being noted. In general, however, it was clear that there was a gradation of activity of the four viruses, which, in the order of their strength, were N.D.V.>swine influenza>influenza B>influenza A. Irrespective of whichever virus was used, the Rh-negative cells invariably *gave negative results.*

Burnet et al.[1] have shown that virus-treated cells become panagglutinable in many mammalian sera. We have confirmed their results with all four viruses, using human serum. With the few normal human sera tested, however, the panagglutinin rarely exceeded a titre of 1/4. The normal human sera diluted 1/32, which were used as controls, agglutinated neither Rh-positive nor Rh-negative human cells which had been treated with viruses.

DISCUSSION

The observations of Pickles[2] on the effect of cholera filtrate on red cells may, as she has stated, help towards elucidating the properties of the "incomplete" Rh antibodies. In the same way these experiments may help in the understanding of virus action on red cells and of the nature of "incomplete" antibodies. At the moment nothing can be said on the mechanism of the reaction. It is interesting, however, to recall that both the viruses and the cholera-filtrate factor apparently exert three analogous sets of actions on red cells. They remove virus receptors, produce panagglutinability, and render appropriate cells susceptible to agglutination by the "incomplete" Rh antibody.

Normal allantoic and amniotic fluid from twelve-day-old chick embryos showed no similar action on cells.

As regards the possibility of a soluble component in the virus-infected fluid being responsible for the modification of the cells, filtration of the N.D.V. preparation through a 0·16μ gradocol membrane removed both the hæmagglutinating activity and its capacity to render appropriate cells susceptible to agglutination by the "incomplete" antibody. This does not exclude the adsorption of any soluble factor by the filter.

SUMMARY

The treatment of human red cells of appropriate Rh genotype with certain viruses of the influenza group renders the cells susceptible to agglutination by the "incomplete" anti-*D* Rh antibody.

We wish to thank Dr. A. E. Mourant, of the Blood-Group Reference Laboratory, Lister Institute, for supplying the serum containing the "incomplete" anti-D Rh antibody.

Medical Societies

ROYAL SOCIETY OF MEDICINE

Laboratory Diagnosis of Virus Infections

The pathology section of the society met on March 18, with Dr. A. B. ROSHER, *the president, in the chair.*

SMALLPOX

Prof. A. W. DOWNIE said that in the early eruptive stage of smallpox scrapings from a papule or the base of a vesicle smeared on a slide and stained by Gutstein's method will often reveal large numbers of elementary bodies which, while not diagnostic, are highly suggestive of smallpox. The most reliable test is the complement-fixation reaction of Craigie, using macerated crusts or vesicle fluid as antigen (6 crusts or fluid from 6 vesicles is enough) and a rabbit antivaccinial serum as antibody. The results can be reported within 24 hours. Another very useful test is the characteristic lesion on the chorio-allantoic membrane of the chick embryo, which is elicited with the scantiest material but takes 2–3 days to develop. The demonstration of antibodies in the patient's serum may be used as a late confirmatory test; but while the reaction is usually positive in smallpox it may also be positive with sera from recently vaccinated persons (such as smallpox contacts are likely to be), so it cannot be regarded as specific.

INFLUENZA

Dr. J. A. DUDGEON described the methods used for the laboratory diagnosis of influenza A and B. For the demonstration of the virus during the early stages of infection, throat garglings may be instilled intranasally into ferrets, which may or may not show clinical signs of influenza but usually develop specific antibodies. In typical virus-A epidemics the proportion of clinical takes in the ferret is high, but in mild or sporadic infections and in virus-B influenza diagnosis may have to depend on a specific antibody response. Alternatively, throat washings or sputum treated with penicillin and sulphadiazine is inoculated on to the chorio-allantoic membrane, or preferably into the amniotic cavity of the chick embryo, which is tested after 4 days' incubation for the presence of virus, using the red-cell agglutination technique with both guineapig and fowl blood. Again, better results are obtained with this technique in virus-A than in virus-B infections. A significant rise in antibody titre in the patient's serum during convalescence is also a useful index to the diagnosis, using either the red-cell agglutination test or the complement-fixation reaction. Samples of blood should be taken at onset and 10–14 days later; to avoid a hæmolysed specimen the serum should be separated as quickly as possible from the clot.

PSITTACOSIS-LYMPHOGRANULOMA GROUP

Prof. S. P. BEDSON, F.R.S., pointed to the close serological association between the viruses of psittacosis, *ornithosis*, and lymphogranuloma venereum, and the looser link between these and the viruses of trachoma, inclusion conjunctivitis, and mouse and cat pneumonia. These are large viruses of 150–250 mμ diameter; they stain readily and specifically, and show a developmental cycle. While direct microscopical examination is not usually possible with material from human cases of suspected psittacosis, Castenada-stained smears of the spleen or air sacs of infected birds (fulmars, pigeons, and fowls, besides the parrot family, may be affected) will often yield positive results. Virus particles can also be demonstrated in the large mononuclear cells of pus from a lymphogranuloma bubo. Mice are readily infected intraperitoneally or intranasally with sputum from cases of psittacosis, the intranasal route being particularly useful for pigeon strains; the chick embryo is also susceptible. Pus from lymphogranuloma buboes may be injected intracerebrally into mice or into the yolk-sac of the developing chick. As in other infections the complement-fixation test may be used for diagnosis in this group when it is *no longer* possible to isolate the virus; but the reaction is not specific, since positive results from cases of lymphogranuloma may be obtained with psittacosis-virus antigen as well as with the homologous virus. There is the same lack of specificity with the Frei skin test.

NEUROTROPIC VIRUSES

In discussing the large group of neurotropic viruses, Dr. F. O. MACCALLUM said the most important point in laboratory diagnosis was the proper collection and preservation of material, such as cerebrospinal fluid, throat garglings, blood, and post-mortem tissue; most *viruses survive best if kept at the lowest possible temperature*. In the various types of encephalitis, much more common in the U.S.A. than here, and in louping-ill, the virus can rarely be isolated from cerebrospinal fluid; the most suitable material is tissue from the central nervous system, but specific antibody can usually be demonstrated in convalescence. In lymphocytic choriomeningitis, mumps meningo-encephalitis, and herpetic encephalitis the virus can most readily be recovered from cerebrospinal fluid or blood by inoculation of either laboratory animals or the chick embryo.

DISCUSSION

Dr. J. CRAIGIE, F.R.S., pointed out that vaccinia virus contained a stable (S) and labile (L) antigen, and that for the complement-fixation test rabbit serum containing the S antibody was essential. Dr. MERVYN GORDON, F.R.S., asked if an agglutination reaction might serve to distinguish lymphogranuloma from psittacosis. Prof. WILSON SMITH remarked on the epidemiological value of laboratory diagnosis in virus infections, but thought a negative reaction—e.g., in suspected influenza—had a very limited value. Prof. RONALD HARE said his experience in the isolation and identification of influenza virus in Canada had been very similar to that recorded by Dr. Dudgeon. Dr. J. M. ALSTON doubted whether the techniques described could be used at present by the clinical pathologist; and the PRESIDENT suggested that a pamphlet indicating the material required for diagnosis, and how and where it was to be sent, would be useful. In answer to a question, it was stated that antibody could be demonstrated by the seventh or eighth day of most virus infections, and probably reached its maximum titre in 2–4 weeks.

Reviews of Books

Textbook of Midwifery

(2nd ed.) WILFRED SHAW, M.D., F.R.C.S., F.R.C.O.G., surgeon-in-charge, gynæcological and obstetrical department, St. Bartholomew's Hospital, London. London: J. & A. Churchill. Pp. 649. 21*s*.

THIS substantial volume begins with an introduction containing some sound advice on the care of the pregnant and parturient woman; the student would be wise to read it when he has reached the last page of the book. In the section on the physiology of reproduction the anatomy and physiology are well up to date, and the text, besides being easy to read, is enhanced by beautifully clear illustrations of early ova. The section on clinical midwifery includes the physiology and management of pregnancy, normal labour, and the puerperium. The account of management of the first stage of labour is largely a detailed and careful description of how to perform a vaginal examination, and not enough is said about the management of the patient, her feeding, the avoidance of retention of urine, and many other points. The dangers of pituitary extract are discussed: Mr. Shaw believes that these have been exaggerated and that, used with intelligence and skill, it is perhaps the most useful drug in practical midwifery. In this he treads on thin ice, for subsequently 'Pitocin' is advised in the treatment of hæmorrhage in the third stage of labour, in postpartum hæmorrhage, and in the treatment of primary and secondary inertia. He successfully points out the different, and often conflicting, opinions held on various forms of treatment, but in the chapters on delivery of the breech, on the management of suspected disproportion, and on antepartum hæmorrhage, the wisdom of this policy is questionable, since it masks the valuable lead he could give from his own experiences. In his desire to be fair to others, Mr. Shaw has not perhaps been kind enough to himself, and the book als contains much dead wood that might well be cleare away. Even mention of such things as de Ribes ba in the treatment of placenta prævia, the induction o labour by bougies, the stomach-tube, the hydrostati bag, and the use of antistreptococcal serum in puerpera sepsis might be regarded as unnecessary in such a wor as this: their place, now, is surely in a history of midwifery. In the section on the resuscitation of the bab *born in white asphyxia, three illustrations of an uncovere* baby being revived by artificial respiration hardly bea out his sound assertion that the guiding principle should be to avoid rough handling.

In Darkest Germany

VICTOR GOLLANCZ. London: Gollancz. Pp. 128. 8*s*. 6*d*

WITH no claims to literary form, this is a series of impressions flung together in haste and copiously illustrated. It represents the outcome of a visit to Germany last autumn, when Mr. Gollancz toured a number of the worst areas, including Düren, Aachen, and the Ruhr, and within a few weeks gathered a surprising amount of information. Much of the material has already appeared in letters to newspapers, and is reproduced in its original form. Writing with manifest sincerity, he has in the main managed to avoid sentimentality, and has obviously done his utmost to present facts rather than vague generalities.

The effect of this book must be shocking to anyone who has not become completely case-hardened. Admittedly almost everything he describes—the pallor, the hunger œdema, the "misery of boots," the families huddled together in cellars and ruins—could be paralleled elsewhere, but the *whole story is one* which makes unspeakably depressing reading. It would be misleading to quote single observations, since the author as far as possible keeps to the rules of good propaganda, and when he describes an incident he has observed himself usually he follows it with any relative statistics he has been able to muster. It may be objected that he tells too little of what has been done by Military Government, and too much of what has not; but it is darkest Germany he is describing, and it is his contention that much more must be done for the physical, intellectual, and spiritual needs of Germany if the coming generation is to believe that democracy holds anything better than the Nazi doctrine. However far the reader may go with the author in this belief, he cannot but be affected by the facts related, and the illustrations which, while not in any sense "horror pictures," tell the tale of day-to-day wretchedness and deprivation.

Practical Handbook of the Pathology of the Skin

(3rd ed.) J. M. H. MACLEOD, M.D., F.R.C.P., physician and director of the pathological department, St. John's Hospital for Diseases of the Skin, consulting physician for diseases of the skin, Charing Cross Hospital; I. MUENDE, M.B., M.R.C.P., physician with charge of pathological department and lecturer at St. John's Hospital. London: H. K. Lewis. Pp. 415. 50*s*.

Atlas of Histopathology of the Skin

G. H. PERCIVAL, M.D., PH.D., F.R.C.P.E., Grant professor of dermatology, University of Edinburgh, physician to the skin department, Royal Infirmary, Edinburgh; A. MURRAY DRENNAN, M.D., F.R.C.P.E., professor of pathology in the university, pathologist to the infirmary; T. C. DODDS, F.I.M.L.T., laboratory supervisor in the department of pathology of the university. *Edinburgh E. & S. Livingstone. Pp. 494. 75s.*

THESE two works are complementary. In the new edition of the *Handbook* there has been very little alteration of the text of the second edition, which was almost a complete revision of the first. It is still the standard work on the subject. The *Atlas*, on the other hand, is something quite new, being a splendid collection of 376 first-class coloured photomicrographs, covering a very wide range of skin diseases. The text has been kept to a minimum. Both works are intended for dermatologists, pathologists, and postgraduate students, and an excellent plan for study would be to use them side by side.

TRADE MARK

'INTRAVAL SODIUM'

BRAND

soluble thiopentone

for anaesthesia of short duration and introductory narcosis by the intravenous route

Extensive use over many years has established soluble thiopentone as the most satisfactory product in this class of anaesthetics.

Supplies: ampoules of 0.5 Gm. (each with a 10 c.c. ampoule of sterile distilled water)
ampoules of 1 Gm. (each with a 20 c.c. ampoule of sterile distilled water)

SEVERE BURN *(Area 162 sq. inches)*

A treatment using tulle gras, pressure dressings and plaster fixation

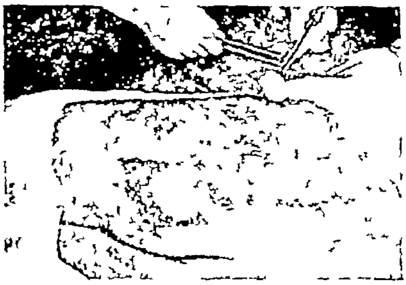

Fig 1

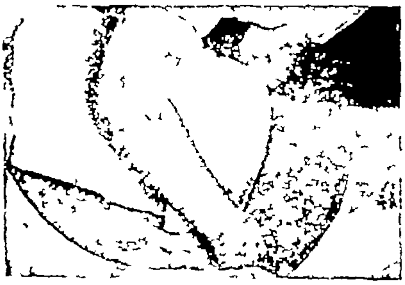

Fig 2

CASE HISTORY—The patient, a young man, was admitted to hospital, having been burnt by an electric blanket The raw area measured 162 square inches. Excision of the burnt area was performed on the same day. Tulle gras (Jelonet) was applied. Fixation by Gypsona plaster of Paris bandages applied over the whole area, abdomen and thigh The patient was given a blood transfusion. Seven days later, the affected part was covered with thin razor grafts from both thighs and a pressure dressing of Elastocrepe applied. Fixation was again secured with Gypsona plaster of Paris.

The patient was discharged to duty 7 weeks later.

The details and illustrations above are of an actual case. T. J. Smith & Nephew Ltd, Hull, manufacturers of Elastoplast, Elastocrepe and Jelonet, are privileged to publish this typical instance of the use of their products with success in the belief that such records will be of interest.

Leprosy in Britain

THE sensational treatment by the lay press of the periodical reports of cases of leprosy in this country is based on the popular tendency to regard such cases as a social problem of the first magnitude and their immediate incarceration as imperative to the public welfare. The unreasoning fear which a diagnosis of leprosy engenders dates from the Middle Ages. In actual fact the chances of dissemination under our modern conditions of life are negligible. It was estimated before the war that there were 250 lepers in the British Isles, and this number has doubtless been augmented by the influx of immigrants from the endemic areas during the last decade. Yet no autochthonous case of infection in Britain has been reported for many years.

Leprosy was at one time common throughout Europe and in this country, but it began to decline in Europe about the fifteenth century; and it has shown no sign of re-establishing itself in Britain in spite of its repeated reintroduction from the tropics and subtropics, where it still flourishes. Our freedom from serious infection can be ascribed to the improvements in personal hygiene and sanitation, and the better standards of housing and of living, with the consequent diminution in child infection. Leprosy is not a highly infectious disease, and the long and intimate association of susceptible persons with an infective case is necessary for the continuance of the disease. Adults are refractory to infection, and probably the majority are immune to leprosy; but children are less resistant and may acquire it from close and protracted contact with "open" cases.

Only a small proportion of cases of leprosy are potentially infective to others. The clinical forms of the disease may broadly be divided into the neural and the lepromatous types, of which the former greatly preponderate in the endemic areas. These neural cases may ultimately suffer from the crippling lesions and deformities associated with secondary nerve changes; but they are not infective to others, since bacilli can rarely be recovered from them and then only in very small numbers after repeated and painstaking search. Such spectacular "closed" cases are of no potential danger to the community. In lepromatous leprosy, on the other hand, which may be difficult to diagnose until the disease is well advanced, the diffuse or nodular lesions on skin and mucous membrane harbour many bacilli. These are "open" cases and the patients are therefore potentially infective to others. In the endemic areas such lepromatous cases constitute but a small minority of the total; but it is their close association with susceptible persons, particularly with children, under squalid conditions, which is largely responsible for the maintenance of the disease in a community. In this country simple regulation of the domestic life of patients with this form of leprosy should be all that is necessary to remove the slight risk of their transmitting the infection to others. Experience has shown that sufferers from leprosy in this country are eager to coöperate fully in their treatment and in measures to prevent the spread of the disease. In rare instances where this is not the case some compulsion might be necessary, but there is no justification for indiscriminate compulsory segregation of all leprosy patients.

While leprosy is insignificant as a social problem in the British Isles, it remains an acute medical one. Treatment is not yet satisfactory, but the prospect of more specific chemotherapeutic remedies is growing brighter. Under the existing medieval attitude to the disease it is virtually impossible to admit a known or suspected case of leprosy to any British hospital or other institution except the one small voluntarily maintained leprosy colony in the south of England. Even a brief stay in hospital for the treatment of some incidental medical or surgical ailment cannot be arranged; and this, together with the needless stigma traditionally attaching to the disease, renders the patient's plight indeed pitiful. Refused employment, ostracised by society, and debarred from hospital facilities, he loses the faith and hope which are essential for his recovery. All he asks is for a more enlightened understanding.

Lymphocytic Meningitis

THE clinical picture of meningitis with an excess of lymphocytes in the cerebrospinal fluid may result from infection by yeasts (torulosis), trypanosomes, spirochætes (syphilis, relapsing fever,[1] and Weil's disease), the tubercle bacillus, and viruses. The viruses which more commonly affect other systems predominantly, the most important being those of mumps, glandular fever,[2 3] infective hepatitis,[4] atypical pneumonia,[5] and psittacosis, may at times cause a meningeal reaction so that the case presents as one of lymphocytic meningitis. The essentially neurotropic viruses of anterior poliomyelitis and herpes zoster cause lymphocytosis in the cerebrospinal fluid and often produce clinical signs of meningitis; in some epidemics of poliomyelitis cases occur where the whole course of the disease is that of a lymphocytic meningitis without clinical evidence of involvement of anterior horn cells, and these are usually considered to be abortive cases of poliomyelitis.

In 1924 WALLGREN[6] described six examples of lymphocytic meningitis in children which he considered to be a separate disease entity and called acute aseptic meningitis; the main characteristics were a fairly sudden fever with symptoms and signs of meningitis, a sterile cerebrospinal fluid containing an excess of lymphocytes, a good prognosis, and absence of complications. The ætiology was obscure until ARMSTRONG and LILLIE,[7] investigating the cause of the St. Louis encephalitis epidemic of 1933, discovered a previously unknown neurotropic virus which could be transmitted to mice and monkeys and was quite distinct from the virus which caused the outbreak of encephalitis. Little was known of the clinical history of the case from which the virus was

first isolated; but subsequent work[8] showed that the clinical picture in man was that of a lymphocytic meningitis similar to that described by WALLGREN, and in view of the intense congestion of the choroid plexus seen in infected animals the disease was named benign lymphocytic choriomeningitis. The virus was subsequently isolated from cases in England[9] and elsewhere, and it was found that a few patients showed clinical evidence of involvement of the brain, spinal cord, and cranial nerves besides the meningitis. It seemed probable, however, that other neurotropic viruses might cause a similar clinical picture, and accounts of two recent small outbreaks bear this out. In this issue Dr. JENNINGS describes 22 cases with clear clinical evidence of meningitis or encephalitis, admitted to one hospital in north-west Middlesex between March and November, 1946. In these there was a lymphocytosis in the cerebrospinal fluid and recovery was the rule, while in several there was involvement of cranial nerves, especially the facial, and three showed signs suggestive of involvement of the spinal cord and one of the cerebellum. In some cases a Paul-Bunnell test was done and it was always negative, which is important in view of TIDY's[2] recent suggestion that glandular fever may be the cause of many cases of lymphocytic meningitis. Attempts were made to isolate the causative virus from the blood and cerebrospinal fluid in some of the cases by inoculation into various animals, without success. KIBBE and BEADENKOPF[10] have described 23 similar cases admitted to an American army hospital near Myitkyina in Burma during June, 1945; there was no evidence of involvement of the cranial nerves, brain, or spinal cord in this group, and all recovered. Extensive virus studies were carried out in these Burmese cases: virus neutralisation tests for the Armstrong virus were negative in the 19 samples tested, and the complement-fixation test was negative in 18 and anticomplementary in 2 samples; similar tests from random cases were also done for the viruses of mumps, St. Louis encephalitis, Japanese (type B) encephalitis, W. Nile type encephalitis, and dengue, and these were all negative.

It appears that benign lymphocytic meningitis can be caused by many different viruses, some known and others not yet isolated. Further elucidation of the problem will require close collaboration between clinicians and workers on viruses, so that blood and cerebrospinal-fluid samples can be obtained at the right stage of the disease for animal inoculation and virus neutralisation and complement-fixation tests. Judging from the clinical picture, the disease process is not necessarily confined to the meninges, and the brain, spinal cord, and cranial nerves may at times be involved; but pathological studies in man are largely lacking, owing to the benign course of the disease. The mode of transmission is still uncertain and may perhaps differ with different viruses. ARMSTRONG suspected that mice act as a reservoir of infection, and his extensive virus neutralisation tests in Washington showed that in 45% of houses infested with mice the animals had been infected with the virus of lymphocytic choriomeningitis. He suggested that the virus is conveyed from mice to man by insect bites, but this has not yet been proved. It may be significant that six of the Middlesex cases came from houses in which there were mice The domestic cat might also repay investigation. But the widespread presence of antibodies to the choriomeningitis virus in the sera of normal people in the U.S.A. suggests that human carriers are at least one source of infection

Treatment of Early Syphilis

THE assessment of new treatments for a chronic disease like syphilis must await the passage of time and the careful compilation of statistics. During the late war the prevalence of this disease in the Allied Forces, and the difficulties of ensuring continued attendance, led to the adoption of shorter and more concentrated schemes of treatment, at first with frequent injections of arsphenoxide, and later, as it became plentiful, with penicillin. Since then some valuable information has been gained, but the place of penicillin in treatment and the best methods of using it are still undefined. Doubts raised by early failures have led British clinicians to supplement penicillin therapy with injections of neoarsphenamine and bismuth, though this cautious procedure will inevitably complicate and delay the final assessment

Syphilis in the rabbit, though very different from that in the human, may give valuable clues to the reaction of *Spirochæta pallida* to remedial drugs EAGLE et al.[1] found that the effectiveness of sodium penicillin against syphilis in the rabbit varied greatly with the method of administration. They used different batches of commercial penicillin, without regard to possible differences in their spirochæticidal activity due to varying proportions of the several types of penicillin. When injections were given four-hourly an increase in the number of injections, and thus in the duration of treatment, greatly reduced the total dose of penicillin required for cure. With eight injections the necessary dose was 80,000 units per kg. body-weight; but this fell to 1600 units/kg. with twenty injections, and to 360 units/kg. with fifty injections. When injections were given twice daily for four days the curative dose was 30,000 units/kg.; but it fell to 1770 units/kg. if the treatment was extended to eight days By giving a fixed number of injections and varying the interval between them it was found that much the same dose was required whether injections were given four-hourly, twice daily, or once daily. Injections given so often as to produce a cumulative effect on the blood-level of penicillin were therapeutically less efficient, suggesting that much of the penicillin was being wasted If the duration of treatment was fixed, effectiveness increased in direct ratio to the number of injections Thus in a four-day period, with injections once daily, twice daily, and four-hourly, the curative doses per kg were 50,000, 20,000, and 1600 units. The conclusion reached was that the effectiveness of penicillin depends on both the tissue concentrations and the time during which these are maintained, but that the time factor is much the more important. Many small injections over a long period were more effective than a few large injections over a short period. Injections once daily seemed as effective as those given four-hourly, but there was some evidence that the optimum interval between injections might be eight to twelve hours. If these results are applicable to the treatment of human syphilis, it seems that sodium penicillin may be injected once or twice daily without loss of efficiency. The factors concerned are the length of treatment, the number and frequency of injections, and the total dose of penicillin, *in that order of importance.* Methods of injection which delay the absorption of penicillin will presumably have the same effect as an increase in the number and frequency of injections.

HELLER [2] has tried to assess the results in early human syphilis of fourteen different methods of rapid treatment, including penicillin alone in varying dosage; penicillin and arsphenoxide, with and without bismuth; and arsphenoxide by intravenous drip or by multiple injections, with and without bismuth. The results were observed after twelve to fifteen months, and in spite of varying standards of observation and tests some important findings emerged. The stage in the disease at which treatment was begun was of great importance, the results for primary syphilis being considerably better than those for secondary syphilis and for cases which had already relapsed. Six schemes of treatment employed penicillin alone, the dosage being 600,000 units in eight days (10,000 units three-hourly), 1,200,000 units in four days (40,000 units three-hourly), 1,200,000 units in eight days (20,000 units three-hourly or 40,000 units six-hourly), and 2,400,000 units in eight or four days (40,000 or 80,000 units three-hourly); and there was little difference in the results obtained. When smaller doses of penicillin were combined with varying amounts of arsphenoxide the effects were much the same; but the addition of bismuth improved the results; and HELLER concludes that any method of penicillin treatment will probably benefit from the addition of bismuth. The proportion of failures in primary syphilis seems to have varied from 15% to 25% with most methods of treatment, but the best results were obtained when treatment was begun while the serum reaction was still negative. For secondary syphilis the results were even less satisfactory. With methods employing penicillin alone or in combination failures varied from 41% to 51%. Much the most effective treatment for this stage was arsphenoxide given by intravenous drip for five days; but this was dangerous treatment, giving a death-rate of 1 in 140 cases, compared with 1 in 1873 with multiple injections of arsphenoxide, 1 in 4312 with penicillin combined with small amounts of arsphenoxide and bismuth, and no deaths with penicillin alone. STERNBERG and LEIFER [3] have studied the case-records of 1400 soldiers of the United States Army treated for early syphilis between June, 1944, and February, 1945. All received 2,400,000 units of sodium penicillin in aqueous solution, sixty injections of 40,000 units each being given three-hourly for seven and a half days, without additional therapy. Of these patients, 84% remained under observation for over nine months after treatment, and the proportion of successes at this stage, as estimated by absence of clinical signs and negative blood-serum reactions, was 98·3% of 517 cases of seronegative primary syphilis, 96·5% of 462 cases of seropositive primary syphilis, and 89·9% of 199 cases of secondary syphilis. An interesting point was the very low incidence of asymptomatic neurosyphilis in patients treated by this method: the cerebrospinal fluid was examined after treatment in 719 patients, in only 5 of whom was it abnormal.

Some of this evidence is conflicting, and taken as a whole it sheds little light on this difficult problem. Doubt as to the precise content of the penicillin used in these studies, in terms of the four crystalline penicillins which it is now known to contain, adds to the general confusion. It is clear that judgment must be reserved; rapid methods of treatment are still in the experimental stage and must be used with the utmost caution. Much could be learnt from a systematic follow-up of the many patients treated in the Services with penicillin alone; their records are available, and most of the men could be traced. Such an investigation would be worth the expenditure in time and money.

Annotations

MENTAL HEALTH AND CRIME

MUCH has been said and written during the last two decades about the increase of crime and delinquency. The gravity of the problem is admitted to be increasing; the attempts to deal with it constructively seem quite inadequate. Dr. J. R. Rees, in his Clarke Hall lecture delivered at Lincoln's Inn on March 26, contributed several sound ideas from his recent experience as chief psychiatric adviser to the Army. He was impressed by the great decrease in sickness and crime which followed the systematic drafting of dull men (of whom the Army received more than its fair share) into manual-labour units. When they were given work entirely within their competence, and friends of their own intellectual level, they became happy and healthy, and contributed much to the Army's effort. Nearly 30% of the whole population, Dr. Rees estimates, are mentally backward, chronically neurotic, or emotionally handicapped. If, he suggests, these "weaker brethren," who commit an unduly high proportion of all the crime, could be put to work and properly led, much adult crime would be prevented.

As a starting-point for the attack on the basic social problem of selfishness, marriage guidance is probably, Dr. Rees thinks, about as good as any other; for clearly if couples married more wisely, they would be better adjusted parents, they would want and love their children, and they would provide happier homes. More and better youth clubs, training for and within industry, vocational guidance, and (on the penological side) better trained and younger magistrates familiar with an enlightened prison system—these are some of the reforms from which he would hope to see a solution grow. There is, in his opinion, plenty of knowledge on which to work, but he emphasises the need for research and for much better coördination of the existing knowledge. Whether his suggestion of a Royal Commission is a good one is, however, open to question. A well-chosen Royal Commission would certainly carry weight, but by the time it published its results the situation might have changed out of recognition. There would, moreover, be no certainty or even probability that the Government of the day would act on its findings. The Criminal Justice Bill of 1938, which everyone admitted went a substantial way in Dr. Rees's direction, is still on its shelf. There is no ready-made answer to the problem.

Dr. Rees said, quite rightly, that all crime is a sign of some personality and character disorder, whether it consists of murder and robbery, or of more respectable offences like income-tax evasion, use of electric current during prohibited hours, or driving too fast in built-up areas. What he did not mention at all was the contribution of society itself to crime. Crime is correctly defined as an infraction of law ; we are only just beginning to realise that both the law and the infraction may be symptoms of a collective character disorder for which we are collectively responsible. Our collective shortcomings are partly responsible for the present tangle of restrictive regulations with their infinite number of new offences ; they have also, by binding upon the weaker brethren burdens they are unable to bear, made inevitable much of the crime which is now beginning to cause us discomfort and anxiety. The problem of crime, while it certainly calls for examination of the offender and his circumstances, calls even more loudly for an examination of the social order against which he offends.

THE MULTIPLICATION OF COAGULATION FACTORS

THE orthodox faith of blood coagulation, based on the four agents, thromboplastin, prothrombin, calcium, and fibrinogen, has been able to survive repeated and determined heretical attacks because it offers the simplest explanation of those facts with which the average physiologist is familiar. It is now becoming clear, however, that only as a framework can it continue to exist. Despite the notorious difficulty of obtaining reproducible results in this field of research it is apparent to even the most conservative that modern findings require a considerable elaboration of the old theory, or a new theory altogether. So far the tendency is to try to fit new facts into the old framework, though to some it may seem that the resulting structure is becoming a little unstable. The additions are in the form of "new factors." Some of these are thought to oppose the action of the accepted clotting mechanism, as, for instance, the antithromboplastin described by Tocantins,[1] which he considers to be present in excess in hæmophilia, and a similar, possibly identical, inhibitor studied by Feissly.[2] On the other side of the balance a number of agents have been added by the recognition of the complex nature of factors previously stated to be simple. Thromboplastin is thought to consist of an enzyme (kinase) and a co-factor of lipoidal nature related to cephalin or lecithin.[3] Kinase itself is probably derived from an inactive precursor in the plasma, studied under the name of "plasmakinen" by Laki.[4] Several workers have come to the conclusion that prothrombin is a complex of at least two components,[5] and even fibrinogen has not preserved its undivided identity.

Now, distinct from these fission products of the old clotting factors, come the new "factors V and VI" described by Owren in our columns last week. The evidence that he puts forward must be accepted as being strongly in favour of the existence in normal plasma of an accessory to thromboplastin and calcium essential to their proper action on prothrombin. In his present communication the evidence for "factor VI" is less convincing, but will no doubt be presented in full later.

The existence of an additional factor of the type postulated by Owren had already been suggested by the work of Fantl and Nance[6] in which they found that, while highly purified preparations of prothrombin could be only slowly converted to thrombin by thromboplastin and calcium, the addition of prothrombin-free plasma resulted in a great acceleration of the reaction. Whether, as seems likely, these findings can be explained on the same basis as those of Owren only future work can determine. In any event a fresh impetus to research on blood coagulation has been given by Owren's observations, and, as always, a new discovery may have unexpectedly wide and exciting results. The case of factor V deficiency he describes is obviously an example of an extremely rare condition, but its intelligent investigation has shown once again how important human material can be to the experimentalist, a fact often ignored in academic circles. It provides, too, still another example of how increasing knowledge appears to reveal an almost infinite complexity underlying even the simplest biological process.

And yet, in this particular instance of blood coagulation, the intricacy seems almost too lavish. Do all these factors, whose number now runs into double figures, really exist in the blood for the express purpose of controlling the occasional conversion of fibrinogen to fibrin, or do they, under other names, take part in other and more continuous metabolic processes ? Or is it, perhaps, that one's dissection of the dynamic whole creates a series of static artefacts ?

DOCTOR DEMAND IN A HEALTH SERVICE

WHEN everyone can get medical advice without paying directly for it, what increase may we expect in the demand for doctors' aid ? Sound planning for a new health service requires some estimate of the amount of professional attention people will want ; and this problem has been studied in Canada, now also engaged on tentative plans for universal State-aided medical care.

Although it would be unwise to apply generally to this country the experience of a particular town in Eastern Canada, yet the results of a morbidity survey made some time ago by Richter[1] in two Nova Scotian communities are certainly relevant. This survey covered a year's record of the services given by the local doctors in Glace Bay, a typical mining town, and Yarmouth, a non-industrial town in the same area. There were differences in the age-sex composition, and the economic and industrial background of the populations, but the most important difference was in the method of providing for medical care. In the mining town a contributory insurance scheme assures treatment by general practitioners, hospital care, operations, drugs, and dressings for each worker and his dependants. In the rather more affluent Yarmouth the fee-per-service system operates, the usual charges being $2 (10s.) for a surgery consultation and $3 (15s.) for a visit. The contributory scheme had been in operation in Glace Bay for about 80 years, and the level of demand had become stabilised. Records were kept of the number of professional services rendered by the practitioners in each town to all members of the communities during the 12 months of the survey, and comparisons between the incidence-rates of *treated* illnesses were then made. Clearly such comparisons were complicated by the occupational, economic, and demographic differences of the two populations, but some of the results which were relatively unaffected by these difficulties are significant.

In both communities two-thirds of the services were given to the workers' dependants, but an important difference was revealed : under the insurance scheme the larger families—with eight or more members—had twice as much medical care as families of the same size had under the *fee-for-service régime*. It appears then that, when assured provision is absent, the larger

1. Richter, L. The Effect of Health Insurance on the Demand for Health Services. *Canad. J. Econ. polit. Sci.* May, 1944, p. 179.

families get less than their share of medical service. Further results also indicate that where economies have to be made the children suffer most because of the financial loss entailed by continued sickness in bread-winner or mother. Generally, the "treated illness" rates at all ages were appreciably higher among the insured population; presumably this does not necessarily reflect any real difference in the incidence of disease but rather an increased readiness to seek a doctor's advice. A cynic might attribute this alacrity to a very human desire to get one's money's worth for one's contribution, but there may be a widespread belief that prompt attention to minor ailments is a preventive of serious disability. Under the insurance scheme common colds, tonsillitis, minor injuries, and digestive upsets are much more often treated by doctors than under the other system. There are differences, too, in the character of the services provided; for the insured patients their doctors made more home visits and dispensed twice as many drugs and four times the number of dressings prescribed by their counterparts in the other town. Home visits, which are more expensive under a fee-for-service system, were much more frequently made to sick children in the mining town.

From all this, those charged with the provision of medical man-power and supplies for our new health service may reasonably infer that the removal of economic restraint may entail a rise of perhaps 50% in the demand for professional attention. For the general practitioners, whose numbers cannot increase in step with this demand, this will mean even heavier calls upon their time and patience—a consideration which might be taken into account in the forthcoming negotiations. Against this, of course, must be set the possibility that readier access to the doctor's care for apparently trivial illness may give fresh scope for the prevention of more serious developments. The balance between sound preventive medicine and merely harassed overwork is very finely set, and much will depend both on the technical and clinical assistance made available and on the good sense of the public.

CONTINUOUS PENICILLIN APPARATUS

THE discomfort of repeated intramuscular injections in the administration of penicillin has stimulated many ingenious minds to contrive apparatus which will maintain a continuous and accurate dosage in small bulk. Most of these depended on hydrostatic principles and were constructed essentially of a calibrated glass tube connected to the injection needle by a necessarily long length of rubber tubing. Unfortunately, however, penicillin may deteriorate on protracted contact with rubber, and such bedside apparatus is in any case easily overset and very temperamental. Attention has therefore turned towards mechanical devices. Professor Fleming's team adapted a clock, deprived of its hands, to drive down the plunger of a syringe, but rubber tubing was still used to connect the syringe to the patient. In this issue Major Bowie and Captain Borcar describe the Secunderabad apparatus, which has the precision workshop of R.E.M.E. behind it. Rubber tubing is eliminated by strapping the syringe to the patient's thigh at the site of injection, using a flexible speedometer-cable to connect the piston mechanism with an electric motor. A rather similar apparatus, designed by Dich and Jensen, was described [1] by P. J. Dragsted, of Copenhagen, to the Danish Society of Internal Medicine in April, 1946. The Danish apparatus is self-contained and driven by clockwork, so that the patient can move about freely without disconnecting the apparatus; the clockwork is silent and runs without attention for 24 hours. The same technical difficulties have occurred to both inventors. However well the syringe plunger seems to fit the barrel there is a tendency for it to leak under continuous pressure. Dragsted advises lubrication with liquid paraffin, while the Secunderabad apparatus is fitted with a plunger of "resilient material" which can be expanded by a tightening device. Another common problem has been to allow for some movement of the intramuscular needle on the fixed syringe. Although this is not shown in their diagram, the Danes say that a short rubber connexion may if necessary be inserted between the nozzle and the needle. In the Secunderabad apparatus an ingenious spring-coiled needle solves this problem but raises others of cleaning and replacement. The syringe appears to be easily removed for recharging in the Danish model, so avoiding the complexity of a three-way tap and recharging syringe.

While clinicians continue to think it important to keep blood-penicillin levels constant there is likely to be a demand for apparatus such as these. If accuracy, ease of maintenance, and simplicity in operation are the criteria, the published descriptions suggest that the Dich-Jensen has some slight advantages over the Secunderabad.

INDUCED VITAMIN DEFICIENCIES

THE investigator who wants to study specific vitamin deficiencies in human subjects finds his material hard to come by. Natural deficiencies are almost always multiple, and the grosser ones usually arise in remote places, such as prisoner-of-war camps, enemy-occupied countries, or the less-frequented parts of the tropics. When his work seems of national importance he may be allotted volunteers—Servicemen or conscientious objectors, perhaps—but otherwise he must rely on himself, his colleagues, or his students, none of whom will relish deprivations extending over years. The late war was remarkable for the painstaking studies made among (and by) prisoners-of-war in the Far East; but there again the deficiencies were multiple and uncontrolled by the investigators.

In the United States Horwitt and colleagues,[1] working for the National Research Council, have studied induced vitamin deficiencies in the inmates of a mental hospital over 2½ years. One group of patients were subjected to a mild chronic thiamine plus riboflavine deficiency over the whole period, and in a second group a more acute deficiency was induced. An obvious drawback to the experiment was that these patients could not be guaranteed to have a normal vitamin metabolism—presumably many of them were schizophrenics, whose metabolism in many fields is grossly deranged. The 36 male patients studied fell into two age-groups of 58–78 and 24–42 years. Each age-group was divided into three classes, A, B, and C, so that each class consisted of 7 old and 5 younger patients. Class A received a daily diet containing 2200 calories and sufficient vitamins except thiamine (400 µg.) and riboflavine (900 µg.). Class B had the same diet with 6 mg. of thiamine and 1·3 mg. of riboflavine added. Class C were the controls, on the usual hospital diet. The clinical effect of the diet in class A was at no time more than minimal. There was some dulling of interest and restriction of activity, but psychological tests were satisfactorily performed. The skin of some of the younger subjects became thinner, making them look older than they were, and some drying, thinning, and wrinkling of the lips was noted. Within nine months from the beginning of the deficient diet, an abnormally high level of lactic and pyruvic acid was found in the blood in response to a standard exercise after ingestion of a standard amount of glucose. This abnormality persisted throughout the experiment.

At the beginning of the third year of the experiment class B were given a daily diet containing only 200 µg. of thiamine and 800 µg. of riboflavine. Within three months their levels of blood lactic and pyruvic acids after the consists of murder and robbery, or of more respectable offences like income-tax evasion, use of electric current during prohibited hours, or driving too fast in built-up areas. What he did not mention at all was the contribution of society itself to crime. Crime is correctly defined as an infraction of law; we are only just beginning to realise that both the law and the infraction may be symptoms of a collective character disorder for which we are collectively responsible. Our collective shortcomings are partly responsible for the present tangle of restrictive regulations with their infinite number of new offences; they have also, by binding upon the weaker brethren burdens they are unable to bear, made inevitable much of the crime which is now beginning to cause us discomfort and anxiety. The problem of crime, while it certainly calls for examination of the offender and his circumstances, calls even more loudly for an examination of the social order against which he offends.

having been caused by horses and horse-drawn vehicles in 1870, against 1087 fatal accidents caused by motors in 1942. On the other hand, better legislation for the care of children is reflected in the fall of deaths in mines: 124 boys aged 10–15 and 10 younger boys died in the mines in 1870, whereas in 1942 only 4 children in all died in "mines and quarries," one of them being a girl under 5. Probably those 4 children were all playing near quarries or old shafts, and were killed accidentally by falls. Gale's tables, indeed, show a sudden decline in deaths from violence in children aged 10–15 from the decade 1851–60, when it was 93 per 100,000 (77 boys, 16 girls) to the decade 1861–70 when it fell to 45—less than half. Below the age of 10 the fall was less dramatic, and it seems certain that legislation to ease the lot of children in industry must be the explanation. Gladstone was forcing his reform Bills on a reluctant Parliament, and public opinion was being influenced by such widely differing books as *Oliver Twist* (1838) Engels's *Conditions of the Working Class in England in* 1844, Mrs. Gaskell's *Mary Barton* (1846), and Kingsley's *Water Babies* (1862).

Deaths from suffocation of children under 5 are still high, having fallen from 947 in 1870 to only 539 in 1942, when there were, in addition, 176 deaths of newborn children from lack of care. Birth injuries cannot be compared in the two groups, since the term evidently had a different meaning in 1870. Deaths on railways fell from 125 to 38, and deaths from drowning (apart from bathing accidents) from 875 to 447. Burns and scalds compete most nearly with traffic accidents as a cause of death, for though they have fallen from 1739 to 513 the number of such preventable accidents is still much too high. Dr. Leonard Colebrook, F.R.S., reminded us not long ago that in the five years 1935–39 6516 people in England and Wales died from burning accidents, and 2825 of these were children; more than 90% of these deaths were due to burning and scalding in the home.[6] Bad housing and overcrowding, old-fashioned grates around which children play for lack of space elsewhere, ill-designed fireplaces, inadequate fireguards, and inflammable clothes combine to produce this terrible waste of life. When non-fatal accidents, many of which lead to loss of function or at best severe scarring, are also taken into account the price of our general carelessness is seen to be appallingly high. In a recent letter[7] Colebrook advocated a simple guard for electric fires which, if widely used, could remove or make negligible at least one important cause of fatal accidents.

LOCAL APPLICATIONS TO PREVENT DENTAL CARIES

ATTENTION has lately been focused on the organic portion of the enamel as the primary site of attack in dental caries. It has been suggested that organisms travel along this organic material until the dentine is reached, and that blockage of the organic paths should check the carious process. In the United States B. Gottlieb has claimed good results from a technique based on this hypothesis. He first applies a 1% solution of 'Naccanol,' which seems to be a wetting agent intended to decrease the surface tension and facilitate better penetration; then a 5% solution of silver nitrate is painted on and left for a minute before precipitation is produced with a saturated solution of calcium chloride. This precipitation is intended to prevent the black stain otherwise found where silver nitrate is applied. A British United Press report says that fairly frequent applications of the solutions are necessary. Now that the formulæ of the solutions have been divulged it will be interesting to see whether further experiments bear out the early somewhat startling claims.

BONES IN THE BANK

A "bone bank," perhaps the first of its kind, has been set up at the Geisenger Memorial Hospital, Pennsylvania.[1] Dr. Leonard Bush, head of the orthopædic department, has explained that surplus bone from such operations as osteotomies can be preserved indefinitely at a temperature of 10° F, and it will provide material for chip grafts, so eliminating one stage of the grafting operation. The value of a bone bank must depend on the kind of material available for storage, and this is likely to be limited to fragments which are partly compact and partly spongy. For filling in defects after trauma or the excision of tumours or cysts, these fragments will be quite satisfactory; for, though heterogenous skin grafts[2] or nerve grafts[3] are unsuitable for transplantation after storage, on account of the foreign protein reaction they excite, with chip grafts it is a matter of indifference whether the bone survives or not. On the other hand, the special properties of living cancellous bone and of massive rigid cortical grafts will still make it desirable to obtain these from the patient himself.

THE CALL-UP

IN the spirited debate at the second reading of the National Service Bill the Minister of Labour explained that any young man training for a trade or profession is to have the option of serving either before or after his apprenticeship; doctors and dentists would, he suggested, be called up usually about the age of 25, though study for higher qualifications would be accepted as grounds for deferment up to the age of 29. He emphasised, however, that no young man who is liable and medically fit will be exempted; the burden is to be the same for all. None will quarrel with this arrangement on grounds of equity. Nevertheless, it may be questioned whether the ruling should be narrowly applied to doctors. The doctor's contribution to the Forces is his trained skill; though there is a particular knack in applying this skill in the Services, it is basically the same skill that he exercises in civilian practice. The trained doctor, like the trained soldier, can be rapidly prepared for war service, and we suggested on March 22 (p. 375) that the whole of his term of national service should not necessarily be spent in the Armed Forces. The Forces may be hard put to it to employ usefully the 2000 or so men who qualify each year; on the other hand, there is great and growing need for medical men in the civilian and other official services, notably in the Colonies.

There is no reason why doctors, more than any other group, should be excused national service. There is, however, every reason, in the present scarcity, for employing them where they are most needed.

CAMBRIDGE APPOINTMENTS

THE appointments to the honorary staff of Addenbrooke's Hospital announced on March 28 mark a further step in the development of the Cambridge postgraduate school of medicine.[4] Prof. R. A. McCance (head of the department of experimental medicine), Prof. J. S. Mitchell (radiotherapeutics), and Prof. H. A. Harris (anatomy) become physicians to the hospital; Prof. H. R. Dean consulting physician; and the readers in the departments of bacteriology, medicine, and morbid histology assistant physicians. As an academic quid pro quo 17 members of the staff of the hospital have been recognised as lecturers of the university.

Lord MORAN has been re-elected president of the Royal College of Physicians of London.

exercise *test rose higher than those of class A.* Shortly afterwards clinical symptoms developed, either acutely or subacutely. These included a non-pitting œdema of the facial skin, especially of the eyelids, without any œdema of the legs; budding of the blood-vessels into the cornea with plexus formation; decreased vibration sense in the legs; and emotionally some loss of inhibitory control *with an exaggeration of psychotic symptoms.* There were wide individual differences in the time it *took for symptoms to develop and in their intensity.* Those who took a long time to develop symptoms on the whole had mild ones. In general the young withstood the deficiency best. Recovery was immediate when an additional 6 mg. of thiamine a day was given.

CERVICOBRACHIAL SYNDROMES

Prof. René Leriche lately remarked[1] *that there are* still a number of unclassified vasomotor syndromes in the arm. He describes, for instance, one of inadequate vasoconstriction marked by paræsthesiæ, redness, and swelling in the fingers, worse in warm weather, and immediately relieved by lying down. He regards this as similar to the condition sometimes seen in the legs after sympathectomy for hypertension, in which vasoconstrictor tone is lost so that the peripheral circulation *cannot adjust itself to changes of position. If this is* the explanation it is a little odd that stellate block should be the right treatment; but Leriche believes that this corrects any existing sympathetic imbalance and is not to be regarded as merely the antidote to vasoconstriction.

In the causation of the various syndromes of the erect position Leriche attaches some importance to compression of the neurovascular bundle in the gap between scalenus anterior and medius, and he suggests that the *significance of congenital anomalies of the lower cervical* transverse processes is possibly that they allow the insertion of scalenus medius to encroach further forward, thanks to its additional origin, so narrowing the gap still more. In costoclavicular compression Leriche holds the unorthodox view that the subclavius is partly responsible, and he advises section of this muscle, or crushing its nerve, in addition to a routine anterior scalenotomy. He does not mention partial resection of the first rib *for this condition, though others find it essential in severe* cases. His general conclusion, however, will be widely acceptable—one should not diagnose Raynaud's disease or acroparæsthesia until postural causes have been entirely excluded; and here the patient's history of his trouble provides the most valuable guide.

At a discussion on pain in the arm at the Royal Society of Medicine on Feb. 4 there was pretty general agreement that brachial neuritis is usually an ill-founded diagnosis *(though acute infective radiculitis is a genuine and* common entity), and that as a rule a mechanical factor can be found. Telford and Mottershead,[2] who have made a systematic investigation of the costoclavicular syndrome at operation, in the dissecting-room, and experimentally in normal students, do not believe that costoclavicular compression is as ubiquitous in these cases as some writers make out. Their observations have shown that forcible depression of the shoulder widens rather than narrows the costoclavicular interval, and they maintain that the disappearance of the radial pulse which often occurs with this movement has nothing to do with the clavicle but is due to squeezing of the axillary artery between the heads of the median nerve. *All surgeons may not agree with* these conclusions of Telford and Mottershead, but their combination of *anatomical investigation* with the experimental clinical approach is the right way to tackle this problem, which still possesses *undiscovered facets.* Two of their observations are certainly valid. The knifelike anterior edge of the scalenus medius is as capable of damaging the neurovascular bundle as is the anterior scalene. And there are a multiplicity of mechanical and postural factors to be considered, several often operating in the same case.

THIOUREA DERIVATIVE AS RAT POISON

SOME of the thiourea derivatives are highly toxic, and one has proved a useful rat poison. Richter[1] fou *that phenyl thiourea was as lethal as strychnine to r* though not very poisonous to man. Owing to its ta however, *it was not very acceptable to the rats as ba* so a search was instituted for a substitute. The fi choice fell on a derivative, alpha-naphthyl-thiourea, blue-grey powder, which clings easily to dry or surfaces, is very stable, and lasts some years witho deteriorating, air and light not affecting it. Its melti point of 184° C allows it to be used in hot places. It *practically insoluble in water. Rats seem unable* distinguish any difference between poisoned bait a that not poisoned, when both are laid together.

To be effective as a poison for rats, alpha-naphth thiourea (ANTU), which is recommended by the Minist of Food,[2] must be consumed in a large enough do (8 mg./kg. of body-weight). Repeated sublethal do *have no cumulative action; on the contrary, they* m produce some tolerance, which may last 30–40 day *The toxicity of* ANTU *is greater to small mamma than to large mammals, and greater to carnivores* th to herbivores. Among rats the toxicity is greatest *Rattus norvegicus* (the brown rat) and least to *R. alexa drinus,* whereas *R. rattus* (the black rat) occupies intermediate position. The toxicity to mice is about t same as to the brown rat. Domestic animals are equall *susceptible, but the effects are minimised* by vomitin (an action which rats are said to be unable to perform[3] *To poison man,* ANTU *would have to be* swallowed a large quantity: no case of poisoning has so far bee reported among makers or users in America, where fift tons have been distributed to 150,000 farms. Neve theless, precautions should be taken, such as colourin *bait containing* ANTU, *laying the bait in sites* inaccessib to children and pets, and washing the hands aft *handling the bait.*

ANTU acts only after ingestion. Contact with the sk is harmless, *but if it is sprinkled on the rats'* runs the can be poisoned by licking it off their paws. The poiso produces an intense pulmonary œdema, due to increase permeability of the capillary walls. McClosky and Smith have reported fatty degeneration of the liver of t "nutmeg" type. A characteristic sign of poisoning a lowered body-temperature. Like the other membe of the thiourea group, ANTU in repeated small dos interferes with the action of the thyroid hormone.

ACCIDENTS TO CHILDREN

VIOLENT deaths of children might be supposed to hav increased with the growth of motor transport; an indeed, from 1911 to 1944 there was a slight but stead rise in deaths from violence among those between t ages of 5 and 15. The overall picture, however, is not dark, for Dr. A. H. Gale[5] has lately published figur showing that the death-rate from all kinds of violenc per 100,000 living, has fallen from 130 in 1851–60 67 in 1940–44 in children under 5, from 54 to 35 in tho aged 5–10, and from 93 to 21 in those aged 10–15. Th numbers at-risk were about the same in the years chose He has analysed child deaths in 1870 under vario headings—such as deaths on railways, in mines, fro burns and scalds, drowning, and suffocation—and h compared them with deaths from similar causes in 194 *The change for the worse in traffic accidents is* ou standing, only 443 fatal accidents in children under

These times are now past, and life is getting less difficult every day, and so is our work. Today nearly every hospital in Holland makes use of the blood-transfusion equipment of the Netherlands Red Cross. Each hospital is visited once a month by the vans of the Red Cross blood-transfusion service to supply them with sterile blood-transfusion sets and dried plasma.

It is very important always to use one standard apparatus, prepared under rigorous control in one and the same laboratory. This makes it possible to prevent nearly all pyrexial reactions after transfusion, which were formerly so common, and it enables us to collect all the transfusion records from the whole country for statistical analysis, a procedure of great value.

In spite of five years' isolation we can now claim that the blood-transfusion service in Holland is not inferior to those in other countries.

SERVICE PSYCHIATRY

In 1942 an expert committee was appointed by the Government to investigate and appraise the work of psychiatrists and psychologists in the Services, and to consider its application to other purposes. This committee was composed as follows:

Sir Wilson Jameson, chairman: Surgeon Vice-Admiral Sir Sheldon Dudley; Air Marshal Sir Harold Whittingham; Lieut.-General Sir Alexander Hood; Lord Moran; Prof. F. C. Bartlett; Prof. D. K. Henderson; Prof. Aubrey Lewis; Prof. A. W. Wolters.

In March, 1943, Sir Wilson Jameson resigned owing to pressure of other duties, and was succeeded in the chair by Sir Francis Fraser.

Their report,[1] dated Jan. 31, 1945, has now been published, and their main findings are summarised below.

WORK OF PSYCHOLOGISTS

The systematic study of the thought and behaviour of humans, the committee consider, can be applied practically to the handling of personnel in all phases of their Service careers, from recruitment through training to readiness for active operations: and this is increasingly recognised at all levels of Service organisation. Experience and tradition accumulated during the war should be preserved and applied in the Services during peace-time.

Psychologists have been mainly engaged in developing methods of personnel selection, so that officers and men could be put to appropriate tasks: in improving methods of training and of assessing proficiency: in assisting in design of weapons and equipment: in studying the psychological aspect of operational problems; and in developing statistical methods for dealing with their material. Much of this work has grown directly from studies made in the 1914–18 war, and from the work of the Industrial Health Research Board, which was first set up in 1918 under the Medical Research Council. Service psychologists have also joined with psychiatrists and experts in other fields to advise on interviewing technique and the use of questionaries, on the use of drugs and vitamins, on job analysis and conditions of work, and on fitness of personality in candidates for various Service duties.

In the Navy psychologists are assisted by technical and clerical staff. The technical staff, mostly W.R.N.S. of high capacity with previous experience as teachers or welfare officers, are trained for a fortnight in the giving of tests. A few male officers are also used, being trained specially in the technique of interviewing, and in the use of oral trade-tests. In the Army the auxiliary staff consists of personnel selection officers and sergeant testers. The officers have a month's training in job analysis, vocational selection, assessment of educational level and occupational experience, and in interviewing technique. Sergeant testers get two or three weeks' training in the nature and use of tests, and must be able to test and score. In the R.A.F. the auxiliary staff are W.A.A.F. clerks who have had four weeks' training and passed an examination.

Differences in the three Services make it impossible to develop the same type of psychological arrangements in each; the pattern must develop to suit the Service; but shortage of trained psychologists in all the Services prevented expansion at the time when the report was written. The committee feel that the universities might be used more fully for laboratory research into Service problems.

They note that, since on demobilisation Service men and women recover their civil rights, the disclosure of Service data about them must be very carefully considered, especially since findings applying to Service situations do not apply directly to employment in civil life.

They recommend that all officers during training should be instructed in the psychological aspects of their work; that psychologists should be represented on scientific and advisory committees and other bodies concerned with personnel; that the senior psychologists should form an inter-Service committee, to discuss developments and research; and that psychologists should be observers at operations or battle exercises. They also suggest directions in which psychological work might be extended, including selection of officers for special duties, design of syllabuses, assessment of proficiency in Service occupations, design of reports on training progress and operational efficiency, opinion surveys, and publicity in the fields of recruitment and hygiene.

WORK OF PSYCHIATRISTS

Service psychiatrists have worked mainly on prevention. They have helped to devise measures to avoid waste of time on the training of people likely to break down, and have studied ways of preventing breakdown and improving morale by placing people in appropriate jobs, with responsibility suited to their intelligence and temperament. Early recognition of symptoms and early treatment have made recovery possible for many patients, who were then allocated to suitable work in the Services or in civil life.

Service psychiatry is naturally based on civil psychiatry. Conscription brought into the Forces many unsuitable people: between a third and a half of all medical invalids, men and women alike, are discharged from the Services on psychiatric grounds—an incidence of 4–10 per 1000 of the average strength per annum. Between a quarter and a third of these have served less than a year. Those who break down in this way show a much higher concentration of ominous signs—such as poor occupational record—than those who do not break down.

In the Navy most psychiatrists now have experience of conditions at sea, and after several months of training begin serving as juniors under a senior Naval psychiatrist. Army psychiatrists, after four weeks' initial training during the war, were posted for four weeks to a field force unit. They were then apprenticed to an area psychiatrist, and their suitability for various types of military psychiatric work assessed. They have no responsibility for treatment or disposal until they have had at least three months' training in the special conditions obtaining in Army psychiatry. In the R.A.F. neuropsychiatric specialists are attached, on entry, to the Central Medical Establishment, for training, and are subsequently sent to a neuropsychiatric centre where they get practical experience under a Service specialist. While in training they spend a period of two or more weeks attached to a station from which squadrons are operating.

Since the aim of Service psychiatry is to make full use of human resources, it gives first place to preventive measures. The psychologist applies selection tests, designed to assess general ability and special skills and aptitudes; the psychiatrist assesses fitness of personality for Service duties; and experience has shown that the methods used give reliable results.

The committee recommends that psychiatrists and psychologists should continue their work of selection, classification, training, and maintenance of mental hygiene and morals; and that better methods should be developed for keeping out of the Forces those who are unsuitable. Better training of those responsible for referring candidates to psychiatrists is needed, while medical officers of units should have more instruction in the handling of psychiatric problems, and officers of units in the maintenance of morale. More psychiatrists than are at present available are needed in the Services, and arrangements should be made, the committee consider, to train suitable medical officers for the purpose. Senior psychiatrists, like senior psychologists, should have some common meeting-ground where they can discuss the procedures developed in each Service.

DUTCH BLOOD-TRANSFUSION SERVICE DURING THE GERMAN OCCUPATION

J. SPAANDER
M.D. Amsterdam
From the Central Laboratories, Netherlands Red Cross, Amsterdam

IN 1939 the imminence of a European war made it necessary to extend the blood-transfusion donor panel in Holland and to prepare for an emergency transfusion service. During the Spanish civil war the treatment of severe casualties with stored blood had proved very promising, and experiments on the storage of blood were started with great enthusiasm in Holland.

In the university clinics of internal medicine at Amsterdam (director, Prof. J. G. G. Borst) an apparatus for blood-transfusion was devised which could be used for taking, storing, transporting, and giving blood aseptically. To gain experience, transfusions with stored blood were performed in five leading hospitals in Amsterdam. Many difficulties, especially in discovering the right kind of glass for the bottles, had to be overcome. However, when on May 10, 1940, the Germans launched their surprise attack and the Dutch Army went into action, 60,000 voluntary donors were ready, and stored whole blood could be sent to the field ambulances and surgical centres immediately.

It was obvious that under German occupation the military blood-transfusion service could not carry on. Yet it was clear to every true patriot in Holland that the forced surrender to the German Army was not the end of the fight. So we had to switch over to a civil transfusion service to prepare secretly for a possible fight for liberation later. The complete equipment of the blood-transfusion service was handed over to the Dutch hospitals through the Netherlands Red Cross. The bottles were prepared in the central laboratories of the Red Cross blood-transfusion service in Amsterdam and delivered to the hospitals. After use the apparatus had to be collected and brought back to the laboratories for sterilisation and refills. Thus many Dutch surgeons and physicians became familiar with blood-transfusion and aware of its advantages in the treatment of shock.

One of our major difficulties was the complete lack of foreign scientific papers, especially English and American. Sometimes, however, we got information, unnoticed by the German censor, through Switzerland and Sweden, and B.B.C. broadcasts told us of the splendid results achieved with dried plasma in the North African and Sicilian campaigns.

UNDERGROUND ACTIVITIES

In spite of strict German control we managed to build a hidden plasma-drying plant in the autumn of 1943. The difficulties in getting machines and materials were manifold. The separator for producing the plasma came from Sweden, together with some " confidential remarks." Several Dutch factories helped us by making the required equipment from raw materials intended by the Germans for their own use.

Thus we managed to prepare 6000 complete sets of dried plasma in 1944. They were divided among several hospitals in Holland, especially in centres where we expected bombing or fighting. In the battles of Nijmegen and Arnhem some hundreds of sets of dried plasma were at hand for resuscitation. The special ambulances of the blood-transfusion service drove as near to the front as possible to provide Dutch civilians and underground forces with plasma and blood-transfusion equipment. Only the day before the liberation of Breda and Hertogenbosch our cars arrived there with plasma and apparatus. During their trips our vans were exposed to machine-gun fire from fighters patrolling over the main roads, but the protection of the Dutch tricolour and the red-cross sign on top of the cars enabled us to continue our duties.

When in September, 1944, many men of the British airborne division from Arnhem were conveyed to Apeldoorn, we succeeded in passing the German sentries and gave the British soldiers the blood-transfusions they urgently needed. Yet some days afterwards the Gestapo intervened and swept aside our humanitarian work.

The Germans continually tried to involve us in their war effort. We became suspicious, with good reason, when they appealed to our generosity. Only when the donor was sure that his blood could not be given to a German was he willing to help. When it became known that blood was being sent to the British soldiers in Apeldoorn, in no time people queued outside the hospital ready to give their blood.

DURING THE LIBERATION

With the approach of the Allied Armies the difficulty in maintaining our services became more acute. In September, 1944, the northern part of our country became isolated from the southern part, and the hospitals in Brabant and Limburg had to rely on their own stock of blood-transfusion equipment.

The Germans stopped all traffic to break the railway strike, so it became extremely difficult to get our cars to the hospitals. In March and April, 1945, only the hospitals in the neighbourhood of Amsterdam could be provided with blood-transfusion sets, which were delivered by bicycle, the cars being requisitioned by the Germans.

Gas works and electricity works were obliged to close down because of shortage of coal. Again we appealed successfully to our friends the Dutch manufacturers. From their hidden stocks we fetched an electricity generator with a Diesel engine, while the German demolition squads were blowing up the cranes of the Amsterdam docks. From the same source we got oil and petrol, hidden in municipal dust-carts. In a German gas-filling station our cylinders were filled with coal gas by a reliable Dutch workman, the empty ones being added to the German cylinders. In this way we had enough gas at our disposal for the laboratory. We hastily erected a small boiler, which was run on coal from German war stores. Many difficulties, many risks had to be faced, but we managed to carry on.

Meanwhile starvation became more and more intense, and everyone tried to find a little more food than the 400 g. of bread and 1000 g. of potatoes allowed per week. Even in this respect we were able to help our employees, owing to the support of many friends of our service When in May, 1945, the first food-flying squadrons arrived at Schiphol and dropped their parcels the men of our laboratory helped to gather the food. They were allowed to eat from tins that had fallen to pieces. I shall always remember the look of satisfaction on their faces when they came back after a day's work !

AFTER THE LIBERATION

Very soon after the liberation we resumed our work on an almost normal scale. The cars, requisitioned by the Germans, were still in Amsterdam, and immediately after the German surrender we gathered the remnants together. After some weeks the cars were ready for use again, and on July 17, 1945, we were able as before to visit every hospital in Holland once a month.

In the meantime people in the southern part of the Netherlands had prepared themselves to give their blood for the starving population of western Holland. Every week hundreds of bottles of blood were prepared in the hospitals of Brabant and Limburg and sent to the central Red Cross laboratories in Amsterdam. From here the blood was distributed to the hospitals in Haarlem, the Hague, Rotterdam, &c.

In England Now

A Running Commentary by Peripatetic Correspondents

I ALWAYS admired men like Owen who from a chip of bone deduced the mighty moa; so when this "thank you" letter from the best-loved Englishman of all time fell into my hands I tried to reconstruct the mood in which he wrote it.

> Victory Dec. 28th 1803.
>
> MY DEAR MACAULY
>
> I have to return you many thanks for all your kindness for sending me milch goats or milch sheep but as they lose all their milk before they get to the Victory I beg that you will not give yourself the trouble and expence of sending me any more. *After the Battle* I may have an opportunity of thanking you in person for all your kindness and attention. My dear Macay Your much obliged
>
> NELSON AND BRONTE
>
> Alex. Macaulay Esq.

The three words in italics show the thought that was to remain aggressive and dominant in his mind for a score of months yet; but underneath this, underneath his habitual courtesy, I think I detect a certain irritability not to be wondered at in a man who left his ship only three times in 27 months and then on the King's business and for less than an hour each time.

The ship was watering off Maddalena and a light wind blew off sea, when suddenly the Admiral smelt a smell—a lusty, loathly smell. "Dammit, what's that?" Sniffing like a hound, he prowls round the busy ship and finds in the bowels thereof a miserable cluster of goats or sheep or both. "Who's supposed to be looking after these?" The wind increases and there is a threat of thunder in the voice. There is much running and scurrying and finally the amateur goatherds are fetched from their watering duties. "Are you supposed to be looking after these *animals*? Then why *don't you*? They stink." Quite a breeze is blowing now. "In any case what are they here for?" One of the chorus of sailors murmurs the word "milk." "Milk? Milk! I haven't seen any milk for six months. What d'you do with it? D'you drink it?" The chorus say the animals are dry when they come aboard. "Then what to purple Providence are we enduring this insanitary . . ."

Half a gale is blowing when an officer comes up. "Mr. Blank. Who is responsible for sending these fetid . . . ?" "A Mr. Macaulay, Sir, sent them as a gift to you, Sir." "O, that fellow! What's he think we are—a purple pound!" Breeze subsides as Admiral retires muttering, but springs up again for a moment when he turns back. "Mr. Blank. Did anyone write and thank Mr. Macaulay?" "No, I don't think so, Sir." "Good Heavens, the manners of the rising generation . . ." Cabin door slams, pen swivels into action. "Turn the ship into a purple pound—poor brutes—how the devil d'you spell Macaulay?"

But perhaps other Lancelots will construe differently.

* * *

"Would THE LANCET like to hear what goes on in your waiting-room?" asked M, an ex-Serviceman home from a sanatorium. "They might," I said, "Jot it down and we'll try it on them."

I always feel embarrassed when I open the surgery door, he wrote, because one momentarily takes the stage. The eyes seem to penetrate through one, and their owners seem to be asking, "What's wrong with him? Doesn't seem much." I must confess that, when I am one of the audience, I in turn become a scrutineer. I find the other occupants more interesting than the weeklies that lie on the table. Some sniff, some cough, some look at the floor deep in thought, others look straight ahead; some just sit and twiddle their thumbs; very few bring a book or even a paper to read. Some look very ill, others the picture of health. But you cannot judge a book by its cover, and the same may apply to patients. You can travel by train from one end of England to the other and never hear a word from your fellow passengers; not so in the waiting-room. Perhaps illness makes the whole world kin, but here we all seem anxious to explain our aches and pains to one another—maybe just as a preliminary canter before we appear before the doctor. Anyway a great deal of sympathy is expressed; whether genuine or not it is hard to say.

Last evening I sat between two middle-aged ladies, one of whom had a small boy with her. When the doctor called out "Come in" a comfortable shuffle went round the waiting-room, which seemed to say, "Now we won't be long." The first patient to go in was a girl. As soon as she had disappeared the lady on my right leaned across me and whispered to the lady on my left that the girl was going to have her first baby. How she had found this out I do not know. Lady no. 2 replied in a voice for all to hear, "Blimey! Wait till she is like me and 'ad nine of 'em, and reared the lot, four in the Army now." And her whole body shook with merriment. She looked round the waiting-room as if for approval. None was forthcoming, so she turned to her neighbour again, asking, "What's wrong with you, dear?" Some lip talk followed that I sensed rather than heard. I felt my face getting redder, but luckily the doctor called for the next patient. Two people got up at once, an old man and a young woman. "It's my turn next," said the old man. "It certainly isn't!" exclaimed the young woman. All eyes were on the actors. How was it going to end? The old man, though keeping up the argument, was craftily advancing bit by bit nearer the doctor's open door. A sharp "Come in" from the doctor gave the old man his chance. He was through the door like a two-year-old, leaving the young lady standing.

My two companions were soon at it again. Now it was number one's turn to ask "What's wrong with you, dearie?" "Nothing wrong with me," said no. 2, "I've brought Alfie along. He was climbing over some railings and slipped and cut 'is arm. As if I 'adn't enough trouble. Take yer coat off Alfie, and let the lady look at yer arm." Alfie proceeded to do so. He had a couple of pieces of sheet tied round the wound, and his mother began to unwrap them, but no. 1 stopped her. She didn't want to see any gory sights: she would faint if she looked at it. So Alfie was told to put his coat on again and not make such a noise, or how could the doctor listen to people's chests?

"'e's a proper little devil." (Alfie's mother again.) "I blame the pictures and wireless for a lot of it. The other day a letter come for my eldest girl from 'er sweetheart. (She's getting married shortly.) I put it on the mantelshelf until she got 'ome from work. After 'is nibs here had gone to school I 'appens to glance up at the mantelshelf and to me 'orror the letter'd *disappeared*. I was in a rare old stew, thinking at that very moment he'd be showing the letter to 'is mates. You know how courting couples write to one another? When 'e *come* back from school I 'ad 'im by the ear before he got in the gate. 'Did you take your sister's letter off the mantelshelf?' I asks 'im. 'Let go me ear an' I'll tell yer,' he says. I lets go and he tells me he'd put it under the staircarpet for a bit of fun. Said William on the wireless does them sort of tricks, and never gets biffed. The little monkey. I don't let 'im listen in to 'Just William' any more."

"Next please," called out the doctor, and Alfie and his mother departed. They were so long that some of the patients began to mutter "How much longer is he going to be?" "I've been here half an hour already." (We are all a bit impatient these days.) At last they came out, Alfie looking every bit the hero. "'ad his arm dressed without a tear," his mother was quick to tell us, and with a cheery "Good night all" she passed out into the night.

* * *

Is it true that dogs can't distinguish one colour from another, and therefore live in a neutral-tinted world? And how would you prove it?

At a recent meeting of our family, Colin (8) proposed that the dog should be asked to gaze into a small box where coloured counters could be suddenly substituted for one another. (Me: And how would you know whether the dog noticed the change? Colin: You'd see whether its eyes moved.) Margaret and I, following Pavlov, thought the dog might be trained to distinguish between (*a*) pieces of meat, and (*b*) pieces of 'Plasticine' looking like meat but of a different colour. (Colin: The dog would smell the meat. Me: We'd wait till the dog had a cold.) But the winning answer came from Robin (7)—"Get inside the dog and look out."

Reconstruction

PILLARS OF HEALTH

FROM A CORRESPONDENT

THE Government promise an indefinite period of hardship before our standard of living can be secured. During this period we must distinguish between luxuries and necessities.

Under the National Insurance Act the State has provided comprehensive protection against many of the economic hazards of life—sickness, unemployment, and the infirmity of age. It has taken an important step towards removing the reproach that children are the principal cause of poverty. These are measures of the utmost value in preventive medicine, and it would be tragic if any campaign for retrenchment were to whittle down any of the benefits of this class.

PROMOTION OF HEALTH

By providing security, National Insurance indirectly befriends health. It provides conditions favourable for healthy living even in adversity. Housing, too, is a long-term insurance policy for health, and in the present shortage we cannot afford to forgo one item in its programme. Comfort in the home has a higher health value than tobacco, alcohol, and gambling, although tobacco and alcohol might possibly stake a claim as adjuncts to preventive medicine in an anxious and disordered world. The key to comfort is warmth and the means to warmth is fuel. Children derive no benefit from tobacco, alcohol, and gambling, but warmth is for them a necessity.

There is no absolute shortage of fuel; we can get it if we are prepared to sacrifice other things that we need less. The tragedy of the situation lies in the fact that we waste most of the fuel we have, by inefficient heating appliances and our failure to conserve heat by proper insulation of our dwellings and our heating systems. Comfort should be placed in the forefront of our struggle for health, and the Government ought to take steps before next winter to insist on good insulation and efficient heating appliances, and to give a high priority to domestic fuel at the expense of non-essential industry. Home keeping is an essential national industry, and hot water and space-heating are vital to the health of the family, especially at the extremes of life.

The first condition of health is security, and the second is warmth. We have been cold too long.

The next essential for health is food in sufficient quantity and of good quality. In this respect we have been fortunate during the war years. Paradoxically enough, we shall be faced with a greater risk of subnutrition when food becomes more plentiful, because the unwise and the ignorant will be free to reject nutritious foods and to fill their bellies with windy substitutes. Here the Education Act of 1944 may be our safeguard. The Provision of Milk and Meals Regulations, 1945, establish a school meals service in which "every dinner shall be adequate in quantity and quality so as to be suitable as the main meal of the day for the pupil, shall be well prepared and cooked, and shall be served decently and in good condition."

For the crown of these legislative achievements one naturally turns to the National Health Service Act, to find what it does for the promotion of health. The result is disappointing. The word *health* is used many times, but in most places it seems to be thought synonymous with the prevention or treatment of sickness. A special feature of the plan is the establishment of "health centres"; but if the Government intends that these shall do no more than offer space and facilities for general practice, health promotion will be neglected and we shall have a sickness service. Comfortable words in statutes and statements about the family doctor being "health adviser to the families under his care" do not make a health service. A doctor does not become a teacher by light of nature; he has to learn teaching method.

Nevertheless a well-conceived nation-wide plan for healing the sick can do much to prevent illness and to restore the sick to working capacity. A programme of immunisation against certain common infections will no doubt become part of the service; the study and practice of physical medicine must surely lead to more effective treatment of the chronic rheumatic conditions which make so many lives a misery; and the adoption of mental illness, tuberculosis of the lung, and other deprived children of medicine into the family of general clinical practice should go far to heal the breach between prevention and treatment. If the axe falls, these services ought to be shielded from the blow, and the livelihood of those who take part in them must be secured.

WHAT IS NEEDED

The four pillars of a health service—towards which the Government and people should bend all their efforts in the interests of economy in man-power and money—are:

1. Family security, as provided in our schemes for National Insurance.
2. Housing, to provide space, warmth, and comfort for family life.
3. Food, adequate in quantity and quality.
4. The establishment of real health centres offering scope for promoting the health of families through educational and social activities.

Medicine and the Law

An Admission of Negligence

THE case of Baldwin *v.* Lord and others, decided at Manchester assizes last month, is a happily unusual example of the sort of accidents which can occur in hospitals and elsewhere and which afterwards seem inexplicable. A patient was admitted to the Oldham Royal Infirmary in 1945 in order that a piece of bone from his leg might be grafted into his right wrist. The operation was duly performed, but somehow it happened that the tourniquet, which should have been removed from the leg before the patient left the operating-theatre, was allowed to remain for eleven hours. Blood-transfusion was tried, but the plaintiff collapsed and died. His widow gave evidence at the trial that the deceased had complained of great pain and had tried to get up in order to take the bandage off his leg. A nurse, it was suggested, had omitted to take notice of the complaint.

The widow sued the managers of the infirmary and the two surgeons concerned in the operation. The defendants admitted liability; it was indeed a perfect instance of such a prima-facie case of negligence as would put upon the defendants the onus of proving that they were not at fault. The claim came into court, therefore, merely as a dispute on the amount of damages. Mr. Justice Singleton awarded £4000 with costs to the widow. The deceased had two daughters, aged 14 and 8; out of the total sum awarded, the judge allocated £450 to the former and £600 to the latter.

"... The need for education in nutrition has been steadily gaining recognition. The popular education of war-time has but made more obvious the general lack. Now the demand is for education in schools, in youth welfare centres and in adult education classes, but the question is not always asked: Who is to teach? ... It might be expected that the nursing and medical professions would be able to help, but the teaching of nurses depends on the education of the medical profession and, of medical schools, only a few provide systematic instruction in nutrition."—*Nutr. Abstr. Rev.* Jan. 1947, p. 497.

case in which there might be indications for ligation is much better treated with heparin, which acts just as quickly and effectively but does not involve destruction of a large and valuable blood-vessel.

Prophylactic heparin treatment is employed only in very exceptional cases. The present trend is all towards very early diagnosis followed by intensive heparinisation.

General Hospital, Mariestad, Sweden. GUNNAR BAUER.

STEVENS-JOHNSON SYNDROME

SIR,—We were interested in the articles of Dr. Nellen and of Dr. Murray in your issue of March 15, and in your annotation of March 22, for we have had under our care a female patient suffering from this syndrome.

A woman, aged 30, was admitted to this hospital as an emergency on Jan. 3, 1946. For some days she had felt rather ill, having some vulval irritation, and 3 days before admission a rash had appeared on both hands and feet; on admission this rash was papular on the dorsal aspects of the extremities, the eyelids were inflamed, and there was some vaginal discharge. She had anorexia, a sore throat, and scalding on micturition, but no other symptoms, and no enlargement of lymphatic glands or other abnormal physical signs.

During the next few days the rash spread over the whole body, becoming vesicular, with some bullæ several inches in diameter. The rash involved the eyelids, mouth, gums, and vulva, and there was well-marked œdema of these parts; severe conjunctivitis also developed.

Temperature fluctuated between 99° F and 102° F, settling around 99° F on Jan. 8 and becoming normal 3 days later. The pulse fluctuated between 90 and 120 per min., becoming normal on Jan. 14.

Blister fluid was sterile, and throat swabs negative for Vincent's organisms, diphtheria bacilli, and hæmolytic streptococci; the only other significant finding was a mild polymorphonuclear leucocytosis (86% of 10,800 white cells per c.mm.). Treatment with sulphamezathine, and systemic and local penicillin did not seem to affect the condition materially.

The lesions crusted and disappeared by Jan. 17, leaving no mark; and there was no residual corneal involvement.

A diagnosis of erythema multiforme bullosum was reached on Jan. 7; but it is of interest that the house-physician sent for one of us saying he had admitted a case of smallpox.

The special interest in this case lies in the fact that the patient was female and was 5½ months pregnant on admission. The disease did not influence her pregnancy, for she gave birth to a healthy daughter on April 13, 1946, and both are very well at the time of writing.

The David Lewis Northern Hospital, Liverpool.

R. D. HOTSTON
H. S. PEMBERTON.

ANKYLOSING SPONDYLITIS AND FLUOROSIS

SIR,—Dr. A. M. G. Campbell, in his interesting review of 25 cases of ankylosing spondylitis (March 29), makes no mention of fluorosis, though your own pages have contained at least three articles on the subject in the last thirteen months.

I was entirely ignorant of the condition until I met Dr. T. Ockerse in Pretoria early last year and heard of his original work[1] in associating stippled teeth and ankylosing spondylitis with the water-supply in 805 endemic areas in the Union of South Africa. Your leading article last year (1946, ii, 835) said that "in at least one or two areas in England where dental fluorosis occurs, osteochondral changes in the vertebræ have been discovered" and Lyth's paper (1946, i. 233) showed clearly how this happens in certain parts of China. Ockerse states that chronic endemic dental fluorosis occurs in "practically every country in the world" and illustrates its association with "bamboo spine" by clinical photographs.

Ankylosing spondylitis is so disabling and distressing a condition that it would be a great step forward if something better than mere symptomatic treatment could be found. Its possible association with fluorosis in this country does suggest an opportunity for useful research, and perhaps the young orthopædic surgeon is the man likely to see most examples of the disease. The general aspect of the subject was surveyed by Murray and Wilson in your issue of Dec. 7, 1946, and they gave a bibliography which should be a useful starting-point for any orthopædic investigator.

London, W.1. ERIC I. LLOYD.

MARRIAGE GUIDANCE

SIR,—Dr. E. F. Griffith's interesting article of Feb. 1 shows that getting married is a serious undertaking concerning which a large number of considerations ought to be taken into account, eugenic, physical, and psychological.

One question of much social significance arises from his article. I would like Dr. Griffith to tell us whether he believes that love, as ordinarily understood, is a proper basis for successful marriage. A great deal, of course, has been written on the theme, much of it, however, in my opinion, vitiated by sentimentality.

Wilde makes a character in one of his plays remark that being in love is really no excuse for getting married. Freud, in the course of his researches, many years ago described love as an abnormal state of mind—an excellent starting point for a serious discussion of the subject.

London, W.1. FREDERICK DILLON.

COMPRESSION OF MEDIAN NERVE IN CARPAL TUNNEL

SIR,—I fear Dr. Russell Brain (March 29) has misread my letter (March 22): I advocated immobilisation primarily as a diagnostic measure. In ulnar neuritis due to friction at the elbow the diagnosis is usually relatively certain, and I quite agree that early operation is indicated.

In conditions such as the costoclavicular syndrome and compression of the median nerve at the wrist the diagnosis is often much less certain. Under these circumstances improvement following immobilisation provides valuable confirmatory evidence of local pressure on the nerve.

In some cases immobilisation appears to give permanent relief; if symptoms recur, then the nerve should be explored and, with the reasonable certainty that there is local pressure, exploration should be thorough.

Liverpool. R. ROAF.

DOCTORS' SALARIES

SIR,—The Misses Gorst and Corbishley (March 29) find that £2 10s. a week is sufficient on which to feed two persons. In so far as the necessities of life are concerned they are extravagant. Common hospitality, however, has to be taken into consideration; and if the doctor of the future is going to take no part in intelligent discussion and social intercourse during his leisure hours, then the standard of British medical practice, which is already in jeopardy, is doomed to fall.

I should also like to point out that an assessment of the doctor's salary at ten times that of the average worker reflects a sad lack of arithmetical ability.

ANOTHER CHIEF ASSISTANT'S WIFE.

SIR,—How curious the confusion of faith revealed by your young lady communicants beneath this heading! Working-class solidarity prompts them not only to degrade their professional aspiration to that of the artisan but to shake their minatory fingers at me because I do not choose to do likewise. "How *dare* he spend so much!"

I have no doubt that it is possible to live, after a fashion, and in canteens, upon the sum with which one of them nourishes her husband and herself; I merely do not regard it either as praiseworthy or desirable. And the strange thing is that if they were the wives of miners or of lorry-drivers neither would they. They would be screaming and fighting for higher wages, less work, more privileges, nylon stockings, and turkey.

The fact is of course they are attuned to their age as I am not; and, when and if these young persons qualify to practise our profession, the Government they doubtless helped to elect will be gladdened, perhaps, by two new embryo Summerskills shrilly denouncing, *ex capella*, the

Letters to the Editor

SOCIAL PATHOLOGY

SIR,—The excellence of the first two-thirds of your leader of March 29 made the defects of the last paragraph conspicuous. Such an admirable appreciation of the theory of social pathology deserved a better discussion of its practice.

Apparently there is still lacking a proper understanding of the individual's relationship to society. If he were in society in the sense in which he may be in the bus or the train which carries him to his daily work, the reasoning of your last paragraph might be sounder. But in addition to being in society he is *of* society, and it is a dangerous fallacy to assume that we need merely study the health of the individual "against a wider background." What society does to the individual and what the individual does and is in society are inseparable, so that social medicine requires not only social pathology but social physiology, social diagnostics, and social therapeutics, each of which will deal not only with the health and sickness of the individual as a member of society but with the health and sickness of society itself. It seems clear that the physician whose starting-point is the old conception of disease as a clinical entity in a biological individual has a long road to travel and much to unlearn before he is a true practitioner of social medicine. Professor Crew, who suggests the inclusion of the anatomy, physiology, and pathology of society in the very beginning of the medical curriculum, offers not only a realistic method but a shrewd commentary on medicine in the past.

There are, of course, "elder statesmen" of public health who see social medicine as something bounded by the limits of the routine which they have long practised. But there are clinicians who decry social medicine as a dangerous new fad and others who see it as a "racket" which it may be expedient to capture. If your feeling that social medicine cannot grow out of "traditional public health" is based upon knowledge of the former, I would but suggest that there are panes of glass in both rows of houses! The importance of the public-health service in the establishment of social medicine lies in the fact that it is already a part of social physiology and social therapeutics; it may not be the whole of social medicine, but it has a larger social-medicine content than any other branch of medical activity.

Most disturbing of all the implications of your last paragraph is the suggestion that public-health officers would turn social medicine into "a science of herd management," a suggestion which must be based upon ignorance of present tendencies in public health. I have had exceptional opportunities of contact with, at any rate, the middle and younger generations of my public-health colleagues, and I have been forcibly impressed by the extent to which "human medicine" guides and is practised in public-health work. It is quite true that we make use of group techniques, for social groups are society's organs; but we are fully aware of the individual in the group, just as we are aware of the group which contains the individual.

I have suggested elsewhere that the essential feature of social medicine is that it contains a philosophy of health—a "social discipline" complementary to the "academic discipline" which Professor Ryle has found in it. Let us select our social physicians in accordance not with whence they come but with where they are going. The acceptance of the right philosophy of health is, clearly, the fundamental qualification. If that is present, the reformed clinician and the enlightened public-health officer can be coequal partners in social medicine—so long as they have the integrity to realise and admit that neither of them holds the whole in his own two hands.

JOHN D. KERSHAW.

Public Health Department, Colchester.

SIR,—In King's College Medical School, Newcastle-upon-Tyne, the Nuffield department of industrial health is already attempting to practise many of the precepts so ably preached in your leading article of March 29. Its laboratories are within the medical school, and its beds, through the generosity of the two physicians concerned, are contained within the clinics of the professor of medicine and the senior honorary physician. It is to be hoped, however, that the interest of social pathology will not turn away too quickly from what you describe as "the old concern . . . with the mechanical environment of man." There is still a great field for study here along the lines of war-time personnel research, for much of preventive industrial medicine, especially the study of fatigue and accidents, is a mixture of applied physiology and engineering; and nowhere, indeed, is this more obvious than in the medieval conditions found in coal-mining.

This department itself studies individual patients, and moreover has sat down not only alongside physicians but (almost literally) alongside those much tougher nuts—surgeons. For in Newcastle the doors of the rooms of the professors of surgery and industrial health face each other across a narrow passage, and a plan has already been drawn up for the joint study of a condition usually considered to be purely surgical.

On the staff of the department is a lady almoner who brings to the bedside information both about the domestic lives the patients lead and the places where they lead them; and at the bedside, too, this is welded on to the equivalent knowledge of where the patient works, which is gathered if necessary by a factory visit. This material is set out in one specially designed note folder, thus enabling the department to abide by the terms of reference which it has set itself—namely, to study and to teach the triple and reciprocal relation between health, job, and social state. Moreover, the close connexion between these three is maintained in the ward, in the outpatient department, and in teaching, which takes the form of an informal discussion, usually of a single case, between a clinical member of the department, the lady almoner, and not more than eight students. Here the whole emphasis is placed upon the patient's history, and the ætiology and management of his or her condition. As part of the course in general medicine, every Newcastle medical student attends eight of these discussions and a few—but very few—lectures.

Field studies and statistical techniques are important research procedures, but they have little place either at the bedside or in the alteration of the emphasis in the future doctor's training. This very necessary reorientation will surely come about much more commonly, in the future as in the past, by a new inspiration which will arise from within hospital practice. This will then help social and industrial medicine to serve both the individual patient and student in some way like the experimental method outlined above.

Our department, begotten by war-time experience out of hospital medicine, and staffed by a team whose ages range from 35 to 21 years, has indeed followed Professor Ryle's lead; but at the same time it is attempting to develop an approach to medicine which will fit the needs of an industrial society such as that of the North East of England.

R. C. BROWNE.

Medical School, King's College,
Newcastle-upon-Tyne.

POSTOPERATIVE PULMONARY EMBOLISM

SIR,—While agreeing in general with your leading article of March 22, I should like to refer to one problem, the solution of which does not seem to you to be satisfactorily settled. What should be done when very early thrombosis has been revealed by pain on palpation of calf muscles or hyperextension of the foot?

My own experience, gained by observation of 300 cases of proven thrombosis and backed by exactly similar results from several other Swedish clinics, tends to show that these cases are very effectively treated with heparin in rather large doses for 4–5 days. After that time all symptoms of thrombosis have usually subsided and the patient may be allowed out of bed. In no single case have we seen an extension of the thrombotic process after heparinisation was started. Even in more advanced cases in which, in addition to the process in the calf veins, there was a long and freely waving thrombus in the femoral vein, no harm arose from the use of heparin. We have never seen such a clot break off and form an embolus once proper heparin therapy was instituted.

Accordingly, the American practice of vein ligation is not at all favoured in Sweden. In fact it is felt that every work for local health authorities—i.e., immunisation and vaccination—the proceeds will not count towards pension, nor will they earn him an independent pension from the local authority. This refusal to reckon in *all* remuneration from every branch of the national service suggests a complete misunderstanding of the general practitioner's worth and work, and is apparently decided upon only to facilitate the work of accountants along familiar lines.

The fact that the Ministry refuses to recognise that there is any shadow of impropriety in treating general practitioners in this manner is of particularly ill omen and assuredly threatens the smooth operation of the new service. The Medical Practitioners Union is not represented upon the Negotiating Committee, nor does it usually see eye to eye with the British Medical Association, but it certainly looks as if it may be forced to urge upon its members an attitude not very different from that of the latter body, although for different reasons. No-one wants to see doctors on strike; but if we general practitioners are to be deliberately treated as of less account than administrative officials in Whitehall and elsewhere, and if even reasonable representations are to be turned down as those above mentioned have been, then the strike is bound to come and the very best that can be hoped for is an unhappy and therefore inefficient service.

GORDON WARD

Sevenoaks. Vice-President, Medical Practitioners Union.

OVERSEAS APPLICATIONS FOR APPOINTMENTS

SIR,—My *Lancet* comes direct, without forwarding either in the United Kingdom or in India. The issue of Jan. 18 arrived on March 1. In the advertisement columns of that issue are listed 172 appointments for which a last date of application is stated. The distribution of these dates is interesting:

"Immediately," "at once," "forthwith" or "as soon as possible"	45
Between Jan. 20 and Jan. 31	61
" Feb. 1 and Feb. 10	39
" Feb. 11 and Feb. 20	12
" Feb. 21 and Feb. 28	6
" March 1 and March 10	5
" March 11 and March 20	2
" March 21 and March 31	2
	172

Thus only 4 of these 172 advertisements could have been answered in time by doctors serving in India.

I did not wish to apply for any of these posts, and can therefore write without personal bitterness. But so long as these remain typical figures I hope you will not allow it to be suggested in your pages that doctors serving in the Forces overseas are given a fair opportunity to apply for jobs.

India. MAJOR, R.A.M.C.

ASCORBIC-ACID METABOLISM OF BANTU SOLDIERS

SIR,—I have read the paper by Professor Kekwick, Dr. Wright, and Dr. Raper (March 29) with some interest since just ten years ago R. E. Bernstein and I produced "a study of the vitamin-C nutrition of healthy Europeans, Bantu mine recruits, and subscorbutic Bantu subjects" in the *South African Journal of Medical Science* (1937, 2, 37). Our conclusions were substantially the same, as the following summary indicates.

1. On a vitamin-C-restricted diet the hourly and daily excretion of vitamin C by Europeans, who ordinarily took large amounts of the vitamin, was much higher than that of healthy Bantu mine recruits.
2. On giving test doses of ascorbic acid the Europeans studied showed an immediately accelerated excretion, and within the following 24 hours eliminated the greater proportion of the added vitamin; the Bantus gave no such response as their tissues retained the added vitamin. This indicated that the Bantu was far less saturated than the European.
3. The highest degree of unsaturation was found in subscorbutic subjects, judging both from their daily excretion and from their response to added vitamin C.
4. The bodily store could be saturated in the healthy Bantu by addition of vitamin C in large amounts to his diet.
5. It was concluded that the difference between the bodily saturation of European and Bantu and the greater liability of the latter to scorbutic conditions depends on difference in dietary intake of vitamin C and not to any physiological peculiarity in the Bantu.

Our investigation was less extensive than that of Professor Kekwick and his colleagues, for in those days it was difficult and expensive to get ascorbic acid in South Africa. We noted, however, in general conformity with their results, that one apparently healthy Bantu mineworker required nearly 3 g. of ascorbic acid to increase his excretion to a level comparable to that of Europeans.

Department of Human Anatomy, Oxford. J. S. WEINER.

SERVICE MEDICINE

SIR,—In his letter of April 5 "R.A.F. Medical Officer" states that a Service medical officer should be an officer first and a doctor second. Fortunately, he implies that this is necessary only in preventive medicine. I repeat, fortunately, for if this dogma is adhered to in treatment the result is deplorable. It leads to such abuses as the patient having to "parade" sick irrespective of his condition; the patient lying "to attention" in bed whilst the C.O. of the hospital does his round; and to attempts to over-rule clinical decisions by superior rank. Such things happened but very rarely in the war-time medical service of the R.A.F., but they are the results of medical officers being officers first and doctors second. If he is not to betray the Hippocratic oath a medical officer must always be a doctor first and an officer second; and in my experience the personnel were best handled by those who followed this principle.

EX-R.A.F.V.R. MEDICAL OFFICER.

THE CURRICULUM

SIR,—I hasten to congratulate Professor Zuckerman and his colleagues in the University of Birmingham for having adopted so boldly a scheme for the reintegration of anatomy and physiology (March 29, p. 395). It is a policy which we in this university favour strongly, though for the time being we are testing it, not in the whole preclinical curriculum, but in one or two of its sections—i.e., special senses and neurology. We shall watch with interest the Birmingham scheme in the hope that we also shall be able to adopt one on similar lines.

It is perhaps worth recalling that the principle involved finds favour with the General Medical Council and is expressed in the latest recommendations as to professional education by the phrase ". . . throughout the period of preclinical studies every effort should be made to secure close correlation between Anatomy and Physiology."

Two points of criticism of the Birmingham scheme come to my mind; and doubtless these will be met if, in the light of experience, they prove to be well founded. The load of dissection allotted to the first term appears to be very heavy, coming as it does at a time when students are introduced to a new subject involving a complicated and difficult terminology; and one would have thought in general that they are more fitted to undertake a more intensive burden of dissection at a somewhat later stage of the curriculum, possibly in the second or third terms. This excessive load probably arises from what would be my second criticism, that to a course of the type envisaged six terms rather than five should have been allotted. The additional term would permit a more leisured approach to the highly important subjects of anatomy and physiology, and would provide more time for greater development of lectures and lecture demonstrations in the coördinating series.

Apart from these minor criticisms I feel sure that medical educationists throughout the country will await with interest further news of the results of the Birmingham scheme.

Medical School, King's College,
Newcastle-upon-Tyne. R. B. GREEN.

During March the Voluntary Hospitals Emergency Bed Service, which is run by a joint committee of the King Edward's Hospital Fund and the Voluntary Hospitals Committee, dealt with 1541 cases on behalf of doctors and hospitals. This is an increase of 90% over March, 1946, and decadent frivolity of Camembert before the proletarian virtues of rat-trap.

When the Spanish Republicans seized the pretty ladies on the beach at St. Sebastian, and forced them, clad in dungarees, to clean out the military stables, they admirably symbolised their ugly and envious pretensions. And your correspondents, formidable in their voluntary dungarees, may expect to find me, a little hungry (but that, at all events, *malgré moi*), warmed in the last rays of the long Edwardian afternoon, firmly upon the opposite side of the barricades.

CHIEF ASSISTANT.

TOXICITY OF THIAMINE

SIR,—In your annotation of Feb. 8 (p. 223), you have misquoted our findings regarding the anaphylactic nature of thiamine toxicity in rabbits. We have definitely stated[1] that anaphylaxis played no part in the toxicity of intravenous thiamine in rabbits. However, the rest of your discussion should be widely circulated among the medical profession to call their attention to the fact that thiamine can cause fatalities in high doses (50–100 mg.). Further, these toxic manifestations of the drug can occur regardless of the site of injection but are more often seen after rapid intravenous injections. *The physician should remember that doses of 50–100 mg.* of thiamine by injection are not utilised to any great extent and are rapidly excreted by the body. Also such injections call into play the pharmacological properties of the drug and not its vitamin properties.

SOURCE OF THE RED CELLS

SIR,—In connexion with your leading article of March 29, which mentioned my preliminary note,[2] I should like to emphasise again that, although the changes described are very conspicuous in a traumatised muscle they may also be readily demonstrated in *normal* (uninjured) active muscles.

The controversy whether erythropoiesis is intravascular or extravascular is by no means settled, as can be seen from even the brief discussion of the question in Whitby and Britton's textbook,[3] where, by the way, the conclusion is just opposite to that in your article. Besides, the "erythrogenic" capillaries of Doan are regarded by a number of workers[4, 5] as tissue spaces between the fat cells of the marrow. Quite recently Schleicher[6] found that "the prevalent view that erythrogenic capillaries exist in the bone-marrow of man . . . could not be verified."

Sterile morphological controversy still flourishes, as far as the problem of the normoblast nucleus is concerned. You express agreement with Fieschi and Astaldi,[7] whose findings in bone-marrow cultures did not contribute anything basically new to this particular problem. On the other hand Leitner[8] advocates karyolysis, although the work of Fieschi and Astaldi (at least its greater part) is known to him. La Cour[9] suggests that the nucleus disappears owing to loss of its staining properties. Another group of workers[10, 11] describe erythrocytes budding off from "mitroid erythroblasts." It is remarkable that only the last group are able to substantiate their views with photomicrographs, although the process is admittedly observed in certain conditions only, and seems to represent a rather vestigial phenomenon.

In his comprehensive review of the subject of bone-marrow cultures Bloom[12] tersely observes: "Tissue cultures of this tissue have been very disappointing from the hæmatological point of view, for the cells of the marrow do not continue to form granulocytes and red blood cells."

ESTIMATION OF PENICILLIN IN SERUM

SIR,—I was interested to read the paper by Sir Alexander Fleming and Dr. Smith (March 29, p. 401) in which they describe their micro-method of estimating penicillin in blood-serum, based on the one published by J. Fielding in the *British Medical Journal* of Jan. 25. Since Fielding's paper appeared we have been using as our culture medium 1% glucose in peptone water with Andrade's indicator; serum was omitted. For simplicity and consistent results in penicillin assays and sensitivity tests this appears to be the best thing we have come across yet.

We use a simple modification of the micro-technique for assays. The doubling dilutions of the serum, starting at 1 : 2, are prepared as usual on paraffin slides and inoculated with the Oxford staphylococcus. These are introduced into sterile Dreyer's tubes with a Pasteur pipette. A total of four drops for each dilution is used—two drops of serum and two drops of glucose peptone water and the indicator. Each tube is sealed with a pellet of 'Plasticine,' placed in a Dreyer's rack, and incubated overnight. The results compare favourably with the macro-technique and the end-point is much more easily read than with the capillary-tube technique

M. J. PIVAWER.

THE G.P.'s PENSION

SIR,—Since no word comes out of the secret conclaves of the Negotiating Committee, and none is to be expected until some cry of triumph or excuse for defeat announces the shape of things to come, it seems well that doctors should be enlightened as to one at least of the rods in pickle for them. I refer to the question of pensions for general practitioners. It has long been a claim of the Medical Practitioners Union that pensions should be given, but we certainly did not expect that they would be so arranged as to give the administrative branches *better chances and higher pensions* than general practitioners. It is not surprising that draft regulations should contain clauses which threaten to produce unforeseen hardships, but I will deal now with something much worse—i.e., with regulations which responsible officials of the Ministry refuse to modify in spite of obvious hardships, *with regulations whose ill results must therefore be deemed to have the Minister's approval.*

The general intention of the draft regulations on superannuation is to impose upon the new service those Civil Service rules which have been in operation for many years and, on the whole, satisfactorily. One of these rules ordains that the "remuneration" upon which pensions are to be based shall be average remuneration over the last three years of service. These years are, of course, in the case of an administrative officer, the three years in which his earnings have been highest. This rule would not be fair in the case of general practitioners because their later years are often less prosperous than those of middle life, and it is right that it should be varied. The variation proposed (and, indeed, insisted upon) is that the remuneration of general practitioners shall be based upon the average of all their years of service, and this is obviously unfair to them. The suggestion that they *also should be entitled* to take the average of their three best consecutive years has been utterly rejected.

Again, it is to be noted that the administrative officer, entering the service at the age of 18, and beginning to contribute towards his pension at once, can get in 47 years before the retiring age of 65. His pension is thus potentially larger than any the general practitioner can hope for—i.e., the average of his best three years multiplied by 47, *in place of the average* of all years (good and bad alike) multiplied by 40 or less. Yet the administrative officer brings nothing to the service except his *schooling, no special* degree or qualification; he works much shorter hours; and he takes virtually no responsibility—certainly not the responsibility for life or death, happiness or misery, which is the daily burden of the general practitioner.

Finally, it is to be noted *that, for pension purposes,* the general practitioner may reckon only the receipts from State general practice—i.e., from his *capitation fees,* less a deduction for expenses. Although the Act provides that he must have opportunity for doing certain first six months every medical conscript should serve the rest of his time under conditions that would provide the necessary experience to enable him to fill a civilian post in his profession efficiently on his release.—Mr. NOEL-BAKER replied: I understand that doctors have at least six months' work in hospital after they are qualified and before they are called up for the R.A.F. Many of them are then posted to stations, some of which, no doubt, are isolated; but it is in the stations that most of the medical work of the R.A.F. is done. All general hospitals in the R.A.F., however, organise regular clinical meetings, to which medical officers of surrounding stations are invited. In this way most of our doctors can improve their knowledge if they feel that their ordinary work does not give them experience enough.

Mrs. GOULD: Is the Minister aware that a number of these medical officers have been posted to isolated stations for over a year, where they have not yet had half an hour's work a day to do, and in some cases have never had the opportunity of performing any sort of clinical work which could not have been done by a child of ten?—Mr. NOEL-BAKER: If my hon. friend will give me particulars of special cases I will see if there is anything I can do.

Incidence of Venereal Disease Among Troops

Replying to a question, Mr. F. J. BELLENGER stated that the number of cases of venereal disease reported and treated amongst British troops in the United Kingdom during 1946 was 3·3%.

Public Health

Rising Birth-rate in England and Wales

IN the last three months of 1946 the birth-rate in England and Wales, 20·5 per 1000, was the highest of any December quarter since 1921; the rate for the same quarter in 1945 was 15·3. The Registrar-General, who gives these figures,[1] also reports a death-rate in the quarter of 11·3 per 1000, compared with 11·4 for the same quarter of 1945. The infant-mortality rate was 44 per 1000 related live births—7 below the average rate for the fourth quarter of the ten preceding years.

For the whole year the birth-rate was 19·1 per 1000, the highest since 1923. The approximate reproduction-rate for the year—1·102—exceeds by 10% that required to maintain the population; this is the first time since 1922 that the rate has reached replacement level. Infant mortality, 43 per 1000, was the lowest ever recorded in this country, being 2 per 1000 below that in 1944, the previous lowest.

Smallpox

During the week ended April 5 smallpox has been diagnosed at Scunthorpe, Lincs, and Doncaster, Yorks, in circumstances suggesting association with the recent outbreak at Grimsby. At Bilston, Staffs, the importation of smallpox from India is suspected. At Stepney one secondary case infected in Mile End Hospital was sent to hospital on March 21, since which there have been no further notifications.

At Scunthorpe an unvaccinated platelayer, aged 35 years, living in a common lodging-house, developed a rash on March 22 and was removed to an infectious diseases hospital on the 25th diagnosed as chickenpox. On April 1 laboratory examination suggested smallpox which was confirmed clinically next day, when the man was removed to Laceby Smallpox Hospital. Contacts not recently vaccinated are numerous, and secondary cases are already due to appear; one has been removed on suspicion. Two men who absconded from Grimsby while under surveillance as contacts stayed at the lodging-house at Scunthorpe at a material time. A few crusts were found on one and have been sent for laboratory examination. It is not improbable that other unidentified and itinerant contacts have moved on to other common lodging-houses, so special vigilance should be exercised.

At Doncaster an assistant master at a preparatory school, vaccinated 13 years previously, developed a rash on March 27 and was removed to Doncaster Smallpox Hospital on the 31st. Modified smallpox has been confirmed. Fortunately this patient is believed to have been confined to his residence from the date of appearance of rash and is unlikely to have infected his pupils, who must, nevertheless, be under surveillance. The source of infection is unknown; but a link with Grimsby, through another absconding contact there, is suspected.

At Bilston the infection seems to have been imported by a soldier. This man, vaccinated in infancy, in 1944, and in 1946, left Agra on Feb. 17 for Karachi by train and thence travelled by air via Cairo and Marseilles to Heath Row, where he arrived on the 22nd. He reached Bilston on the 23rd. He developed fever on March 2 and a few spots on March 5. Subsequently, his mother, vaccinated in infancy, became ill on March 19 and developed a rash on the 23rd. Another unvaccinated contact sickened on March 23 and developed a rash on the 25th. Initially chickenpox was diagnosed, but variola virus has been cultured and there is now strong suspicion of smallpox. The rashes, reported to be superficial and centripetal, have given rise to considerable difficulty in diagnosis.

Infectious Disease in England and Wales

WEEK ENDED MARCH 29

Notifications.—Smallpox, 1; scarlet fever, 1317; whooping-cough, 2263; diphtheria, 254; paratyphoid, 3; typhoid, 5; measles (excluding rubella), 10,780; pneumonia (primary or influenzal), 1025; cerebrospinal fever, 115; poliomyelitis, 7; polioencephalitis, 0; encephalitis lethargica, 1; dysentery, 85; puerperal pyrexia, 141; ophthalmia neonatorum, 83. No case of cholera, plague, or typhus was notified during the week.

Deaths.—In 126 great towns there were no deaths from enteric fever, 1 (0) from scarlet fever, 3 (1) from diphtheria, 21 (1) from measles, 25 (2) from whooping-cough, 74 (10) from diarrhœa and enteritis under two years, and 38 (3) from influenza. The figures in parentheses are those for London itself.

The number of stillbirths notified during the week was 286 (corresponding to a rate of 26 per thousand total births), including 38 in London.

Obituary

ROBERT GEORGE BANNERMAN

M.D. EDIN.

DR. R. G. Bannerman, who died on March 26, was born in Edinburgh in 1891 and educated at George Watson's College and the University of Edinburgh. He graduated in arts in 1910 and in medicine with first-class honours four years later. As a student he had a distinguished career, winning Vans Dunlop scholarships in 1911 and 1912 and serving as president of the Royal Medical Society of Edinburgh. For a time he was assistant to the professor of pathology in Edinburgh and during the 1914–18 war he served as a captain in the R.A.M.C. On demobilisation he was appointed assistant pathologist to the Royal Sussex County Hospital at Brighton. Later, while holding a grant from the Medical Research Council, as assistant M.O. at the English Sanatorium at Montaña and at the Children's Hospital, Alton, he studied the biological action of light. He also held appointments as pathologist at the Royal Northern Infirmary, Inverness, the Miller General Hospital, Greenwich, and the Paddington Green Children's Hospital. His published work included papers on the fate of tubercle bacilli in human plasma and on the clinical significance of blood platelets. In 1939 he rejoined the R.A.M.C. and was for a time attached to an anti-aircraft brigade near Bristol. In 1940 he returned to his laboratory, and a colleague with whom he worked in the early years of the war writes: "R. G. B. was a shy man who eschewed publicity and ambition—yet he could look back on a busy life in which he had made a substantial contribution to the science of pathology, notably in hæmatology. With those who were afflicted he had a gentle touch and warm sympathy. A cultured man with an appreciation and understanding of literature and music, he was also an effective teller of stories of his student days in Edinburgh."

Parliament

ON THE FLOOR OF THE HOUSE

THE House adjourned on April 3 for the Easter recess, which will give Ministers and M.P.'s a chance of sitting back and taking stock of *the shape of things to come*—and things already past.

During the spring and summer the country must build up a reserve of 10 million tons of coal, to add to the existing reserve of 5 million, for the essential margin of safety is 15 million tons. It is going to be a tight squeeze, and the domestic consumer will be asked to make a substantial contribution by voluntary saving. But the Government, despite some opposition, have announced that they are ready to buy coal from abroad if it can be provided from some source that will not upset our friends in Europe.

Shortages are general in Europe, and indeed in most parts of the world which have been in the war. Our own, although it is unpleasant *to face the facts*, have been smaller than those of many countries both among victors and vanquished. Food continues to be short in many countries, but still no major world epidemic has shown itself, *though tuberculosis in* some countries has reached high figures. Does the absence of a world epidemic indicate a higher general level of food-supply than in the period 1918–21, or is it due to better distribution of food, or to more efficient medical services in the world as a whole? The answer is important in view of the Budget, for on taxation depend prices and subsidies and hence to some extent the general level of nutrition.

The Budget will be opened on April 15, the day the House meets after the recess. Will the Chancellor be able to reduce the general level of income-tax, or to raise the limit of exempt income, or to exempt any part of overtime earnings from tax? And shall we be able to maintain food subsidies at the rate of £400 million a year?

Another way to economise would be by reducing the strength of the Armed Forces. The Government have fixed a figure for the run-down to March, 1948. The T.U.C. ask that this level shall be reached by Dec. 31, 1947. *And it is probable that this is the kind of limit in which economies may be possible.* Otherwise, in this period of change from war to peace organisation, while we are trying to make the United Nations the foundation of a long and perhaps permanent peace, drastic cuts in military expenditure will not be possible. And so long as this period of uncertainty lasts so long will our military commitments and all our shortages and those of other nations continue.

The shortages do not, however, extend to plans for world rehabilitation. The F.A.O. mission for Greece have published a report which, if applied, would put Greece on her feet and make her self-supporting. Yet the plan would cost only 100 million dollars, or about a quarter of the proposed American loan to Greece, which would be largely spent on military expenses. And if Greece with its unsteady economy can be put on its own feet so can any part of Europe. More will be heard of the F.A.O. proposals, but they were published in Washington and are not yet available here. A speed-up in this respect would be of great advantage.

MEDICUS, M.P.

FROM THE PRESS GALLERY

The Age of the Call-up

In moving the second reading of the National Service Bill in the Commons on March 31 Mr. G. A. Isaacs, Minister of Labour and National Service, *said that the age* of calling-up was to be between 18 and 26. The usual call-up age would be 18, but the extra age-limit had been put in to allow the Ministry to make deferments. There was a provision *to allow young men who applied to be* called up from the age of 17½. This provision had been made to enable young men going up to a university, or to some other training course, to come out of the Forces a little earlier to start their university or other scholastic careers. There was also a variation for doctors and dentists. In normal circumstances doctors and dentists would be called up round about the age of 25; but there would be many who were taking specialist courses; and when a man asked for an extension his call-up might *be postponed up to the age of 29.* That had been done to meet the needs of the professions, so that men would get their additional training. The arrangement was also of advantage to the Services, because they would have within their ranks men with higher qualifications to assist in the professional work of the doctors and dentists in the Forces.

After two days debate an amendment for rejection, moved by Mr. RHYS DAVIES from the Labour benches, was negatived by 386 votes to 85, and the Bill was then read a second time. The Government are now considering reduction *of the period of service from 18 months to 12*

QUESTION TIME

Regional Hospital Boards

Mr. W. M. F. VANE asked the Minister of Health whether he was satisfied that the five days given for the consideration, in his department, of the representations which he had invited to his draft proposals for regional hospital boards in December, 1946, was sufficient; whether he was aware that no acknowledgment was received by Westmorland county council to their criticisms of his proposals until five weeks after the publication of S.R. and O. no. 2168; and whether he would ensure that such treatment of responsible local authorities by his department was not repeated in future.—Mr. JOHN EDWARDS replied: The Minister reviewed personally all comments received. The resulting order was published, with notices in the press, on the day it was laid. This seemed a reasonable way of indicating the decision to all who had commented. No discourtesy was intended by the absence of separate replies to all by letter.

Care of the Aged

Mr. GEORGE THOMAS asked the Minister whether provision would be made under his new health scheme for special hostels to cater for old-age pensioners who were bedridden.—Mr. EDWARDS replied: The care of all the aged who are sick will be a matter for the new health service. The care of those who need care but are not sick will be dealt with in further legislation.

Recruitment of Nurses

Mr. PETER FREEMAN asked the Minister how many extra nurses had been obtained this year as a result of his recent appeal; whether the present position was satisfactory; and what further steps were contemplated.—Mr. EDWARDS replied: Over 1000 persons, including 600 qualified nurses, assistant nurses, and midwives, have taken up employment in hospitals as a result of the recent appeal for part-time staff in London. Many more are needed, and recruitment measures are being continued and extended.

Doctors in the R.A.F.

Mr. SOMERVILLE HASTINGS asked the Secretary of State for Air what peace-time conditions in the R.A.F. made necessary a 30% increase in the medical personnel over war-time strength.—Mr. PHILIP NOEL-BAKER replied: Since the end of the war the R.A.F. has taken over some hospital work from the Army; it now depends largely on short-term medical officers, who must start by sharing their work with *an experienced man; the numbers on each station* have decreased, but medical officers are still required. Nevertheless, as I said last week, I share the anxieties expressed, and I propose to consider the matter again. Mr. HASTINGS: Is the Minister convinced that the conditions which he has described warrant such a heavy increase as 30% over war-time strength?—Mr. NOEL-BAKER: I think that they more than explain the increase. Whether we ought to have made a greater effort to reduce below the level which we have now reached is exactly the question which I am going to reconsider with other Service Ministers. Mr. L. D. GAMMANS: Is it true that there is a 30% increase as compared with war-time?—Mr. NOEL-BAKER: Yes, sir. The rate was 2·29 per 1000 in May, 1945, and it is now 3·03. The Army have gone down a little and the Navy have gone up a little. All are substantially above the agreed rate.

"Medical Conscripts"

Mrs. AYRTON GOULD asked the Minister if he was aware that young medical officers, who were called up as soon as they were qualified, were *posted to isolated camps* where they could get practically no clinical experience and there was little work of any kind for them to do; that often they remained in these posts for a year or more; and if he would see that after the

Notes and News

BUREAU OF INTERNATIONAL MEDICAL CONGRESSES

At a preparatory conference, held in Paris in March under the auspices of Unesco, 13 representatives of international congresses and associations in medical science, together with a representative of the interim commission of the World Health Organisation and a representative of the World Medical Association, arranged for the summoning of a conference in October to create the permanent Bureau of International Medical Congresses. The bureau is to coördinate the international congresses of medical science, and to serve as a channel for material aid from Unesco to them. It is also hoped to establish an International Council of Medical Science to advise Unesco on questions referred to it by the Economic and Social Council.

The following directives laid down by the general conference of Unesco on scientific activities may be taken as basis for the work of the bureau:

To assist scientific work of international significance by grants-in-aid and the sending of scientific and technical assistance by means of personnel on missions to national institutions. Amongst the kinds of assistance given would be support of type-culture collections (bacteria, algæ, fungi, genetic mutants) with a view to the preparation of a world catalogue of the strains maintained.

To investigate the improvement of the circulation of scientific literature.

To facilitate the travel of scientists across national boundaries.

To keep the people of all countries informed as to the bearing of scientific discoveries on international problems.

To investigate the possibilities of setting up new international scientific laboratories and observatories.

To investigate the feasibility of smaller projects, such as the creation of international stockrooms for pure substances not commercially available—e.g., radioactive isotopes and pure-line strains of laboratory animals.

The following delegates to the preparatory conference will serve on the committee organising the conference: Dr. Cavaillon, Professor Maisin, Dr. Martínez Báez, Prof. E. Bezançon, Prof. A. Gigon, and Dr. Léopold Mayer. Dr. Kenneth Soddy (National Council for Mental Hygiene) will also serve on the committee.

A JOURNAL ON CARE OF CHILDREN

The Council of Associated Children's Homes have published a new quarterly review, *Child Care*, which promises to be useful to those interested in the welfare of homeless children. The council represent Dr. Barnado's Homes, the Catholic Child Welfare Council, the Church of England Children's Society, the National Children's Home, the Jewish Board of Guardians, and other similar societies. One of the council's chief aims is to foster training schemes for child-care workers, and they have, since the publication of the interim report of the Curtis Committee (on the subject of such training), founded a new training college at Sutton Coldfield. The new journal, under the editorship of the Rev. John W. Waterhouse, vice-principal of the National Children's Home, contains an article by Miss Myra Curtis setting out the main aspects of home life which are important to the child—personal affection, stability, opportunity, and the sense of belonging to a small friendly group of people—and which those given the task of caring for homeless children must seek to replace. The journal, which is well arranged and produced, should make it easy for the great and small voluntary agencies engaged in this important work to share ideas and study old and new aspects of their task in the light of both inside and outside opinion.

GIFTS TO HOSPITALS

As a result of the amendments made in the House of Lords the provisions in the National Health Service Act governing hospital endowments differ considerably from those set out in the Bill. The Hospitals Association has now published a memorandum[1] explaining how donors can ensure that the hospital of their choice may retain their gifts under the new service. In the will or deed of gift, the memorandum points out, it must be made clear that the gift is to be treated as a capital fund separate from the general funds of the hospital. But should a donor wish to help a hospital with its maintenance charges during the interim period the income of such a gift may be used for this purpose until the appointed day. After that date the hospital management committee would be free to use the whole fund, both capital and income, for purposes other than general maintenance connected with their group of hospitals, including the hospital indicated by the donor. Suggested forms of words for use in making gifts, which have been prepared by Chancery counsel, are included in the memorandum.

HOSPITAL LIBRARIANS

The Library Association have introduced a specialist certificate for hospital librarians in their final examination. The syllabus for the certificate is divided into two parts—the first dealing with the patients and the hospital and the second with the librarian and his equipment for the work.

At a course of lectures given to prepare candidates for this new qualification the lecturers included Dr. O. W. Roberts, medical superintendent of Dulwich Hospital, Mrs. Mackenzie, lecturer to the Royal College of Nursing, Mrs. Paget Cooke, who is in charge of the library at St. Bartholomew's Hospital, Captain J. E. Stone, consultant on finance to King Edward's Hospital Fund, and Mrs. Askwith, who is in charge of the patients' library at the Middlesex Hospital. Members of the course also visited Guy's Hospital and the Middlesex Hospital to see the conditions of the work.

PNEUMATIC BONE-SAW

The new pneumatic bone-saw produced by Desoutter Bros. Ltd. is not a reversion to the rather cumbersome pneumatic tools of the twenties but a product of the factory bench. It is very light and easy to handle; it has a pistol grip, and the speed is controllable from zero to 2500 r.p.m. by a trigger control resembling the throttle of a motor-car. The cost, £15 10*s*., is low for such an instrument, and the construction is simple. The saw has to be sterilised by hot air, and it works from compressed-air cylinders with a reducing valve. Trials in all kinds of bone surgery confirm that it is a very good tool indeed.

University of Oxford

An election of two members of the board of the faculty of medicine will be held on June 3.

The electorate consists of all Oxford graduates in medicine who are members of convocation. Nominations will be received up to 10 A.M. on Wednesday, May 14, by the secretary of faculties, University Registry, Oxford, from whom further particulars may be had.

University of London

Dr. Alfred Schweitzer has been appointed reader in experimental physiology at University College, and Dr. J. R. Gilmour reader in morbid anatomy at the London Hospital medical college. Both will take up their appointments on Oct. 1.

Dr. Schweitzer graduated in medicine at Cologne in 1932 and took his PH.D. Lond. in 1940. Since 1943 he has been lecturer in physiology at the University of Leeds. While working in the department of physiology at the Middlesex Hospital in 1941 he published, jointly with Buttle and Kekwick, an experimental evaluation of blood substitutes in the treatment of hæmorrhage. He obtained his D.SC. Lond. last week.

Dr. Gilmour, who qualified in 1931 from the London Hospital, took his M.R.C.P. in 1933 and two years later was awarded a scholarship of the Grocers' Company. In 1936 he was appointed junior assistant director of the Bernhard Baron Institute at the London Hospital. His published work includes papers on the anatomy of the parathyroid gland, intranuclear inclusion in the genital tract, and erythroblastosis fœtalis.

University of Manchester

Dr. C. S. D. Don has been appointed lecturer in medicine and Mr. D. S. Poole Wilson lecturer in urological surgery. The department of industrial health will in future be described as the Nuffield department of occupational health, and the following have been appointed lecturers in the subject: Mr. Thomas Bedford, D.SC., Dr. S. B. Davis, and Dr. Alice Peters.

Royal College of Physicians of London

On Tuesday and Thursday, April 15 and 17, at 5 P.M., Dr. J. Purdon Martin will deliver the Lumleian lectures at the college, Pall Mall East, S.W.1. He is to speak on Consciousness and its Disturbances considered from the Neurological Aspect.

Royal College of Surgeons of England

On Wednesday, April 16, at 3.30 P.M., Dr. James Craigie, F.R.S., will deliver an Imperial Cancer Research Fund lecture at the college. He will speak on Relationships of Virus and Host Cell with reference to Latent and Cryptic Infections.

Applications are invited for election to the office of Hunterian professor, Arris and Gale lecturer, Arnott demonstrator, and Erasmus Wilson demonstrator for the ensuing year. Applications must be made in proper form by April 28, and particulars may be had from the assistant secretary.

---

[1] Obtainable from the British Hospitals Association, 52, Green Street, London, W.1., price 3*d*.

HAROLD MUIR EVANS

M.D. LOND., F.R.C.S.

Dr. H. M. Evans, who died at his home at Beccles in Suffolk on March 28, was a doctor whom practice among the fishermen of Lowestoft had led to the study of marine biology, and his work on the physiology of venomous fish won him recognition within and without medicine. He read papers before the Royal Society; University College elected him to their fellowship; and the Royal College of Surgeons under a special by-law to theirs.

Born at Richmond, Surrey, in 1866, he was educated at Bute House, University College Hospital, London, and the University of Berlin. In 1889 he took the Conjoint qualification and the following year his M.B. After serving for two years as medical officer for the Cape Government Railways on the Bloemfontein Vaal River extension he returned to London to become registrar at the Central London Throat and Ear Hospital, and in 1893 he took his M.D. He then settled in practice at Lowestoft, and joined the staff of the Lowestoft and East Suffolk Hospital as surgeon; during the 1914–18 war he served as surgeon specialist in casualty-clearing stations with the rank of major. His pleasantly written books, which even at their most technical retained a tang of the sea, included a *Short History of the Thames Estuary*, *Brain and Body of Fish*, and in 1943 *Sling-fish and Seafarer*.

Dr. Evans married in 1896 Miss Violet Reid, of Hanworth, and they had two sons and a daughter.

Mr. ARTHUR W. DOWN, founder of Down Bros. Ltd., the surgical instrument makers, died at Croydon on April 2, in his 95th year. He entered the surgical instrument industry in 1866, and was actively interested in the control of his firm from its foundation in 1879 until the last few days of his life.

Births, Marriages, and Deaths

BIRTHS

ALEXANDER.—On March 27, in London, the wife of Dr. Alfred B. Alexander—a son.

BROWNE.—On April 5, in London, the wife of Mr. Denis Browne, F.R.C.S.—a son.

CLYDE.—On April 1, at Surbiton, the wife of Dr. J. O. Clyde—a son.

DALE-BUSSELL.—On March 27, at Newmarket, the wife of Dr. A. P. Dale-Bussell—a son.

FOSTER-SMITH.—On April 6, at Westcliff-on-Sea, the wife of Dr. G. C. Foster-Smith—a son.

HALL.—On March 27, at Eastbourne, the wife of Surgeon Lieutenant Derek Hall, R.N.V.R.—a son.

MCSWEENEY.—On March 30, at Hove, the wife of Dr. M. P. McSweeney—a son.

MARSHALL.—On March 29, at Sutton, the wife of Dr. J. K. Marshall—a daughter.

MORRISON.—On March 27, at Isle of Sheppey, the wife of Dr. J. Neill Morrison—a son.

PATON.—On March 26, in London, the wife of Dr. Ian Paton—a son.

RICHARDS.—On April 4, at Cardiff, the wife of Mr. R. D. Richards, F.R.C.S.—a son.

STEVENS.—On March 26, at Maidenhead, the wife of Lieut.-Colonel C. P. Stevens, M.B.E., R.A.M.C.—a daughter.

SWEET.—On March 5, at Glasgow, the wife of Dr. H. S. Sweet—a son.

TAYLOR.—On April 3, the wife of Dr. A. W. O. Taylor, of Edinburgh—a daughter.

THURSTON.—On April 2, at Oxford, the wife of Dr. J. G. Thurston—a son.

WALTER.—On March 29, at Windsor, the wife of Dr. K. H. Walter—a daughter.

MARRIAGES

EDWARDS—WILLIAMS.—On March 27, at Sutton, Surrey, Errol M. Edwards, M.R.C.S., captain R.A.M.C., to Hetty Williams.

DEATHS

BANNERMAN.—On March 26, in London, Robert George Bannerman, M.D. Edin.

CUMMING.—On April 3, in Malta, Charles Chevin Cumming, C.B., M.B. Glasg., colonel, late R.A.M.C., aged 72.

EVANS.—On March 28, at Beccles, Suffolk, Harold Muir Evans, M.D. Lond., F.R.C.S., aged 80.

FLOYER.—On April 4, at Eastbourne, William Wadham Floyer, M.B. Lond., aged 86

GOURLAY.—On April 5, at Carrbridge, Inverness-shire, Charles Aikman Gourlay, D.S.O., M.D. Glasg., F.R.F.P.S., D.P.H., D.T.M. & H., I.M.S., retd.

NEWLAND.—On March 28, at Cheltenham, Broderick Edward Middleton Newland, L.R.C.P.E., lieut.-colonel I.M.S., retd.

PARSONS.—On March 29, Allan Chilcott Parsons, M.R.C.S., D.P.H., aged 74.

REILLY.—On March 27, Percy George Reilly, M.R.C.S.

Diary of the Week

APRIL 13 TO 19

Monday, 14th

ROYAL COLLEGE OF SURGEONS, Lincoln's Inn Fields, W.C.2
5 P.M. Mr. L. R. Broster: Surgery of the Suprarenal Gland.
6.15 P.M. Dr. W. W. Mushin: Signs of Anæsthesia.
ROYAL SOCIETY OF MEDICINE, 1, Wimpole Street, W.1
5 P.M. *Odontology.* Dr. P. O. Pederson: Dental Investigation of the Greenland Eskimos.
MEDICAL SOCIETY OF LONDON, 11, Chandos Street, W.1
8.30 P.M. Mr. Douglas MacLeod: Endometriosis.
WESTMINSTER HOSPITAL, Horseferry Road, S.W.1
5 P.M. (Meyerstein lecture theatre.) Clinico-pathological demonstration of two cases of hypertension: (1) periarteritis nodosa; (2) tumour of adrenal.

Tuesday, 15th

ROYAL COLLEGE OF PHYSICIANS, Pall Mall East, S.W.1
5 P.M. Dr. J. Purdon Martin: Consciousness and its Disturbances. (First Lumleian lecture.)
ROYAL COLLEGE OF SURGEONS
6.15 P.M. Dr. C. Langton Hewer: Physiology of Anæsthesia.
ROYAL SOCIETY OF MEDICINE
9.30 A.M. *Neurology with the Société de Neurologie de Paris.* Sir Hugh Cairns, Dr. Honor Smith, Dr. C. Worster-Drought, Dr. W. D. Nicol: Penicillin in Neurology.
5.30 P.M. General meeting of fellows.
8.5 P.M. *Pathology.* Dr. J. E. McCartney: Impressions of American Laboratories.
CHELSEA CLINICAL SOCIETY
7 P.M. (South Kensington Hotel, 41, Queen's Gate Terrace, S.W.7.) Mr. Duncan Fitzwilliams: Sir Thomas More and Utopia.
SOCIETY FOR THE STUDY OF ADDICTION
4 P.M. (11, Chandos Street, W.1.) Dr. W. R. Bett, Dr. H. Crichton-Miller, Dr. Denis Hill, Dr. H. Pullar-Strecker, Dr. H. J. Shorvon, Dr. J. Yerbury Dent, Prof. R. C. Browne, Dr. G. R. A. de M. Rudolf: The Uses of Amphetamine.
EUGENICS SOCIETY
5.30 P.M. (Burlington House, Piccadilly, W.1.) Dr. Linford Rees: The Physical Constitution in Mental Illness.
INSTITUTION OF MINING AND METALLURGY
5 P.M. (Royal Institution, Albemarle Street, W.1.) Major-General A. J. Orenstein: History and Prevention of Tuberculosis. (Julius Wernher lecture.)

Wednesday, 16th

ROYAL COLLEGE OF SURGEONS
3.30 P.M. Dr. James Craigie, F.R.S.: Relationships of Virus and Host-cell.
5 P.M. Prof. R. V. Bradlaw: Tumours of the Jaws.
6.15 P.M. Dr. E. A. Pask: Anoxia.
CONFERENCE ON SILICOSIS
10.30 A.M. (at the Royal Institution). Silicosis, Pneumoconiosis and Dust Suppression in Mines. (Opening session.)

Thursday, 17th

ROYAL COLLEGE OF PHYSICIANS
5 P.M. Dr. J. Purdon Martin: Consciousness and its Disturbances. (Last Lumleian lecture.)
ROYAL COLLEGE OF SURGEONS
5 P.M. Prof. B. W. Windeyer: Radiotherapy in the Treatment of Cancer.
6.15 P.M. Dr. T. C. Gray: Curare.
ROYAL SOCIETY OF MEDICINE
9.30 A.M. *Neurology with the Société de Neurologie de Paris.* Prof. T. Alajouanine, Dr. Clovis Vincent: Cerebral Œdema.
BRITISH INSTITUTE OF RADIOLOGY, 32, Welbeck Street, W.1
8 P.M. Prof. R. Sievert: Dangers and Protection in Radiological Work. (Silvanus Thompson lecture.)
UNIVERSITY OF EDINBURGH
5 P.M. (Physiology classroom.) Dr. Douglas Guthrie: The Historical Foundation of Medicine.

Friday, 18th

ROYAL COLLEGE OF SURGEONS
6.15 P.M. Dr. John Gillies: Anæsthesia in Neurosurgery.
WEST LONDON MEDICO-CHIRURGICAL SOCIETY
7.15 P.M. (South Kensington Hotel, 41, Queen's Gate Terrace, S.W.7.) Dr. William Sargant, Mr. Harvey Jackson, Dr. Spencer Paterson: Physical Treatment in Psychiatry.
FACULTY OF RADIOLOGISTS
2.30 P.M. *Therapy.* (Royal College of Surgeons.) Dr. L. M. Shorvon, Dr. W. M. Court Brown, Dr. Frank Ellis: Constitutional Effects of Radiation.
HEBERDEN SOCIETY
5 P.M. (11, Chandos Street, W.1.) Dr. Graham Weddell: The Structure of Striate Muscle in Relation to its Function.

Saturday, 19th

TUBERCULOSIS ASSOCIATION
11 A.M. (King George V Sanatorium, Godalming.) Demonstrations.
2 P.M. Dr. James Watt, Mr. J. E. H. Roberts, Dr. W. E. D. Moore: Complications following Adhesion Section.
3.45 P.M. Miss M. Sheehan: Employment of Tuberculous Staff.

Dr. H. A. Krebs, whose name appeared in the list of new fellows of the Royal Society (*Lancet*, March 29, p. 410), is professor of biochemistry in the University of Sheffield (not Leeds) and honorary biochemist to the Royal Sheffield Infirmary and Hospital.

RECOVERY FROM STARVATION

R. O. MURRAY
M.B.E., M.B. Camb.
LATE LIEUT.-COLONEL R.A.M.C.

DURING the final stages of the war in Europe Allied troops overran many concentration camps and liberated a vast number of prisoners suffering from starvation, which had caused the death of many others before relief arrived. Among the survivors disease was rampant, typhus and tuberculosis being extremely common, and famine diarrhœa almost universal.

Sandbostel concentration camp, which was captured on April 29, 1945, contained over 8000 male political prisoners, mostly Russians and Poles, but representing also many other nationalities and almost every occupation. While most had been of the unskilled labouring type, there were several of high intelligence and great experience. Nearly all were young to middle-aged adults, but a few adolescent boys and elderly men were included. They had been in captivity from six months to six years.

The camp was appallingly overcrowded, about 850 men occupying huts intended for 120. There was virtually no sanitation, and the universal diarrhœa soon caused fouling of the entire area. The daily rations were reported to have consisted of 140 g. of bread, extremely coarse and of poor quality, two half-litre bowls of soup, and a small amount of margarine. The value of this diet is estimated at not more than 500 calories. There was no fair system of distribution, and the greatest share was often obtained by those with the greatest strength.

After liberation about 2000 were considered to be fit to proceed directly to a displaced persons' camp after cleansing and without admission to a medical unit. The remainder were placed under medical care as rapidly as possible. The receiving medical units, expanded to the utmost and provided with all available assistance, soon became grossly overcrowded. To relieve them a convalescent camp was opened on May 12. It is on observations carried out at this camp that this paper is based.

In the circumstances only the barest medical investigations could be carried out, but records were kept of the body-weight of each patient on admission and on discharge, and of the amount of food consumed, with a view to their subsequent correlation. It was hoped that these would provide some information about the speed of recovery and the optimum constitution and amount of the diet to be given to patients recovering from advanced starvation.

Starvation has been investigated in the past both experimentally and in famines, but very few inquiries have been made into the process of recovery in the human adult, and those that have been made deal with individual cases in professional fasters or laboratory workers.

Lipscomb (1945), working at Belsen, used for this purpose three graduated diets for different stages during the process of recovery from starvation. The first had a low value of 800 calories, with a large milk content; the second 1700 calories; and the third 3000 calories.

Leyton (1946), who investigated the effects of slow starvation while himself a prisoner-of-war, considers that the prognosis for recovery from starvation is excellent, provided that no concomitant organic disease is present, and notes that Russians under his care ate everything available without any ill effects.

ADMINISTRATION OF THE CONVALESCENT CAMP

From the first it was appreciated that the patients would require both physical and psychological care. However, such large numbers were involved, because the order to accommodate up to 1000 had been received, that individual care, except in the case of the sick, had to give way to the production of the best possible conditions for the majority. It was made clear to the patients that the camp was under military discipline, even though this was reduced to a minimum. Since all patients were typhus contacts, it was decided to confine them to camp during the period of convalescence.

6451

On arrival the patients were dusted with D.D.T., informed of the method by which the camp was operated, and allotted, by nationalities, to huts, where each man was provided with stretcher, pillow, and blankets and issued with toilet essentials. Next day they were medically examined and weighed. This was periodically repeated until they were finally weighed and re-examined on the day before discharge.

It was arranged with the dispatching medical units that all patients should be ambulant and free from diarrhœa before admission for convalescence. As a result nearly all patients had received from two to three weeks' treatment between liberation and convalescence.

Meals were served at 8 A.M., 12 NOON, 3.30 P.M., and 7 P.M. Eating-utensils and tables were kept scrupulously clean. The dining-rooms were light, airy, and cheerful. Though mess tins only were at first available, these were superseded as soon as possible by crockery. All this was done as part of a general plan to introduce into the surroundings an atmosphere of civilisation.

CONDITION ON ADMISSION

General Condition.—Despite the treatment they had received before admission nearly all the patients presented the same picture both mentally and physically. Apart from the universal desire for food, and the truly voracious appetite they displayed, they were utterly apathetic, dull, and submissive. They conversed hardly at all between themselves, did not express any emotion, and appeared to have little interest in life. Very few wanted to write letters or communicate in any way with the outside world. A cheerful remark would often be met by a completely vacant stare, and carelessness of dress and habit was the rule. At this stage they were all amenable to the very moderate discipline imposed, and almost no initiative whatsoever was shown. This total lack of interest was particularly noted among those who had been only a short time under medical care.

Great changes, however, were observed after a few days. Meal-times became noisy, often with complaints of insufficient food or of petty thieving. Vast quantities of food were consumed, and, if a meal could not be finished, an attempt would be made to smuggle out the remainder. Initiative returned and was particularly directed to methods of obtaining more food, despite the very large diet. Many showed a highly developed form of cunning in this respect, the most notable effort being the theft of a calf from a neighbouring field. This animal was introduced into the camp and slaughtered, and the patients began to eat the meat raw. When this was stopped, and some scraps of meat were buried, the patients waited until they were free from supervision and then recovered and ate the meat. In the early stages these people could not believe that any meal in the future could be anticipated with confidence. Meanwhile all amenities, such as pianos, indoor games, and literature, were eagerly asked for, a small orchestra was formed, and later on games of football were played.

Physical Condition.—Gross emaciation was usually seen, due both to loss of virtually all subcutaneous fat and to extreme wasting of muscle. The absorption of subcutaneous fat made the skin hang in loose folds, particularly on the buttocks, which came to be recognised as the first site in which generalised wasting of tissue became apparent. In advanced cases the anus became clearly visible between the tubera ischii, and owing to the

University of Birmingham

Mr. Lancelot Hogben, D.SC., F.R.S., Mason professor of zoology at Birmingham, has been appointed to the chair of medical statistics in the university.

McGill University

On March 11 the honorary degree of D.SC. of McGill University, Montreal, was conferred on Prof. John Ryle, of Oxford.

Royal College of Obstetricians and Gynæcologists

On Wednesday, May 14, at 5 P.M., Dr. Linton Snaith will deliver the Blair-Bell lecture at the college, 58, Queen Anne Street, London, W.1. He is to speak on Tubal Occlusion.

British Association for the Advancement of Science

Sir Howard Florey, F.R.S., will deliver the Radford Mather lecture at the Regent House, Cambridge, on Friday, May 2, at 5 P.M. His subject is to be Penicillin and other Antibiotics.

Royal Sanitary Institute

At a meeting, to be held at the institute, 90, Buckingham Palace Road, London, S.W.1, on Wednesday, May 14, at 3 P.M., Dr. W. H. Bradley, a senior medical officer of the Ministry of Health, is to open a discussion on the Control of Smallpox.

Faculty of Radiologists

Dr. Gordon E. Richards, of Toronto, will deliver the Skinner lecture before the faculty on Friday afternoon, May 16. His subject is to be the Place of Surgery and of Radiotherapy in the Management of Mammary Cancer. The annual meeting of the faculty will be held at Birmingham on June 27 and 28.

London Jewish Hospital Medical Society

On Thursday, April 17, at 8 P.M., at the West London Synagogue, Seymour Place, W.1, Lord Rothschild, PH.D., will deliver the annual oration. He is to speak on the Problem of Fertilisation. Admission is limited to members and those eligible for membership.

British Association of Urological Surgeons

The annual general meeting of the association will be held in Glasgow on Friday and Saturday, June 13 and 14. The provisional programme includes a discussion on the Treatment of Serious Tumours of the Bladder, to be opened by Mr. Clifford Morson, the president. Further information may be had from the secretary, 45 Lincoln's Inn Fields, London, W.C.2.

Harveian Society of London

The council of the society has selected as the subject for the Buckston Browne essay for 1948 the Mental and Physical Effects of Pain. The prize is open to all doctors registered in the British Isles or Dominions who are under 45 years of age. Essays must be submitted by Oct. 1, 1948. Further particulars may be had from Sir Cecil Wakeley, 14, Devonshire Street, London, W.1.

Watts Eden Fellowships

Dr. T. Watts Eden, who died on Sept. 22, has left two sums, each of £10,000 free of duty, to found, after the death of his widow, two travelling fellowships. The first fellowship, which will be administered by the Royal College of Obstetricians and Gynæcologists, is to encourage the study of obstetrics and gynæcology, and the second, to be administered by the Royal College of Physicians, the study of infancy and early childhood in health and disease.

Australia Wants More British Nurses

British nurses wishing to emigrate to New South Wales are to be given priority in the allocation of passages. The New South Wales minister for immigration is reported by B.U.P. as saying that of the 900 berths available for migrants in 1947, 350 will be allotted to women coming out to work in mental and other hospitals.

Morgan E. Williams Bequest

Grants from this fund will be available to doctors and others engaged in medical work resident in the county of Glamorgan who wish to travel abroad on short visits of medical interest. Applications should be made to the secretary of the Welsh National School of Medicine, 10, The Parade, Cardiff.

Naval Medical Compassionate Fund

A meeting will be held at 3 P.M. on Friday, April 25, at the Medical Department of the Navy, 64, St. James's Street, London, S.W.1, to elect six directors of the fund.

Course on Reablement

The British Council for Rehabilitation is holding a course at Nottingham on April 29, 30, and May 1. The speakers will include Mr. S. A. S. Malkin, Mr. J. P. Campbell, Dr. G. F. Keatinge, Mr. E. A. Nicoll, and Dr. T. A. Lloyd-Davies. The council's address is 32, Shaftesbury Avenue, London, W.1.

Institute of Hospital Administrators

The annual conference will be held at the Royal Pavilion, Brighton, next week-end, April 18–20. On the 19th, at 10 A.M., Sir Arthur Rucker, deputy secretary to the Ministry of Health, will speak on Hospital Administration in the New Health Service, and at 2.30 P.M. Mr. B. Lees Read on Financial Implications of the Act. The offices are at Tavistock House North, Tavistock Square, London, W.C.1.

Education of Blind Children

At a meeting of the school medical service group of the Society of Medical Officers of Health, to be held at the Civic Hall, Leeds, on Wednesday, April 30, at 2.20 P.M., Mr. D. D. Stenhouse Stewart, F.R.C.S., and Mr. J. Lumsden, of the Ministry of Education, will open a discussion on the Education of Blind and Partially Sighted Children. The meeting has been arranged at the request of the Minister of Education's advisory committee on handicapped children.

Foreign Awards

The following awards have been made to R.A.M.C. officers:

UNITED STATES

Legion of Merit.—Major-General Sir HENRY TIDY (commander), K.B.E., D.M. Oxfd; Colonel D. C. CHEYNE, O.B.E., M.C., M.D. Aberd.

Bronze Star Medal.—Colonel H. H. KENSHOLE, D.S.O., M.R.C.S., L.D.S.; Major W. G. H. ALLEN, M.D. Durh.; Major A. D. ROBERTSON, M.B. Glasg.

Medal of Freedom with Bronze Palm.—Major G. A. G. PETERKIN, M.B.E., M.B. Edin.

NETHERLANDS

Bronze Lion.—Captain J. W. LOGAN, D.S.O., M.B. Glasg.

Bronze Cross.—Lieut.-Colonel T. D. V. SWINSCOW, M.R.C.S.; Major C. J. LONGLAND, F.R.C.S.; Captain DAVID WRIGHT, M.C., M.B. Glasg.

Return to Practice

The Central Medical War Committee announces that Mr. Charles Gray, F.R.C.S., has resumed civilian practice at 19, Harley Street, London, W.1 (Langham 2579).

Appointments

ALLEN, E. H., M.R.C.S., D.M.R.E.: asst. radiologist, Royal National Orthopædic Hospital, London.

BRADMORE, ROSEMARY, M.B. Edin.: temporary asst. M.O., Kensington.

DAVIES, I. G., M.D. Lond., M.R.C.P., D.P.H.: M.O.H. and schools M.O., Leeds.

DORNHORST, A. C., M.D. Lond., M.R.C.P.: senior asst. to medical unit, St. Thomas's Hospital, London.

GREENE, RAYMOND, D.M. Oxfd, M.R.C.P.: physician, Royal Northern Hospital, London.

HARMAN, J. B., M.D. Camb., F.R.C.P., F.R.C.S.: asst. physician, Royal Cancer Hospital (Free), London.

O'DONNELL, R. F., B.SC., M.B. N.U.I.: pathologist, East Ham Memorial Hospital, London.

St. Mary's Hospital for Women and Children, London:

CULLOTY, TIMOTHY, M.R.C.S., D.M.R.E.: radiologist.
DIMSON, S. B., M.D. Lond., M.R.C.P., D.T.M. & H.: asst. physician.
GORDON, ISAAC, M.D. Lond., M.R.C.P.: asst. physician.
LEWIS, BEATRICE, M.D. Lond.: skin physician.
LUMB, J. R., M.B. Durh., B.HY., D.P.H., D.M.R.E.: radiologist.

Medical Board (Silicosis and Asbestos Scheme, 1931):

Medical officers:
BREBNER, ALLAN, M.B. Aberd.
BULLEID, J. H., M.R.C.S.
CAMPBELL, A. M., D.S.O., O.B.E., M.B. Glasg.
MCGOWAN, R. M., M.B. Glasg.
MACNAIR, R. A. C., M.B. Edin.
ROWLAND, E. M., M.R.C.S.

Colonial Service:

BURNS, J. C., M.B. Belf.: M.O., Malaya.
CANNON, D. A., B.SC., M.B. Glasg., D.T.M. & H.: senior pathologist, Nigeria.
EVANS, W. J. M., M.B. Lond.: M.O., Tanganyika.
HARVERSON, E. S., M.B. Lond.: M.O., Nigeria.
HOAR, C. E. W., M.B. Lond., D.C.P.: pathologist, grade B, Trinidad.
MCLINTOCK, J. S., M.B. Glasg.: M.O., Malaya.
SNODGRASS, R. J., F.R.F.P.S.: deputy director of medical services, Fiji.
WILLIAMS, W., B.SC., M.B.: M.O., Uganda.

RECOVERY FROM STARVATION

R. O. MURRAY
M.B.E., M.B. Camb.
LATE LIEUT.-COLONEL R.A.M.C.

DURING the final stages of the war in Europe Allied troops overran many concentration camps and liberated a vast number of prisoners suffering from starvation, which had caused the death of many others before relief arrived. Among the survivors disease was rampant, typhus and tuberculosis being extremely common, and famine diarrhœa almost universal.

Sandbostel concentration camp, which was captured on April 29, 1945, contained over 8000 male political prisoners, mostly Russians and Poles, but representing also many other nationalities and almost every occupation. While most had been of the unskilled labouring type, there were several of high intelligence and great experience. Nearly all were young to middle-aged adults, but a few adolescent boys and elderly men were included. They had been in captivity from six months to six years.

The camp was appallingly overcrowded, about 850 men occupying huts intended for 120. There was virtually no sanitation, and the universal diarrhœa soon caused fouling of the entire area. The daily rations were reported to have consisted of 140 g. of bread, extremely coarse and of poor quality, two half-litre bowls of soup, and a small amount of margarine. The value of this diet is estimated at not more than 500 calories. There was no fair system of distribution, and the greatest share was often obtained by those with the greatest strength.

After liberation about 2000 were considered to be fit to proceed directly to a displaced persons' camp after cleansing and without admission to a medical unit. The remainder were placed under medical care as rapidly as possible. The receiving medical units, expanded to the utmost and provided with all available assistance, soon became grossly overcrowded. To relieve them a convalescent camp was opened on May 12. It is on observations carried out at this camp that this paper is based.

In the circumstances only the barest medical investigations could be carried out, but records were kept of the body-weight of each patient on admission and on discharge, and of the amount of food consumed, with a view to their subsequent correlation. It was hoped that these would provide some information about the speed of recovery and the optimum constitution and amount of the diet to be given to patients recovering from advanced starvation.

Starvation has been investigated in the past both experimentally and in famines, but very few inquiries have been made into the process of recovery in the human adult, and those that have been made deal with individual cases in professional fasters or laboratory workers.

Lipscomb (1945), working at Belsen, used for this purpose three graduated diets for different stages during the process of recovery from starvation. The first had a low value of 800 calories, with a large milk content; the second 1700 calories; and the third 3000 calories.

Leyton (1946), who investigated the effects of slow starvation while himself a prisoner-of-war, considers that the prognosis for recovery from starvation is excellent, provided that no concomitant organic disease is present, and notes that Russians under his care ate everything available without any ill effects.

ADMINISTRATION OF THE CONVALESCENT CAMP

From the first it was appreciated that the patients would require both physical and psychological care. However, such large numbers were involved, because the order to accommodate up to 1000 had been received, that individual care, except in the case of the sick, had to give way to the production of the best possible conditions for the majority. It was made clear to the patients that the camp was under military discipline, even though this was reduced to a minimum. Since all patients were typhus contacts, it was decided to confine them to camp during the period of convalescence.

Next day they were medically examined and weighed. This was periodically repeated until they were finally weighed and re-examined on the day before discharge.

It was arranged with the dispatching medical units that all patients should be ambulant and free from diarrhœa before admission for convalescence. As a result nearly all patients had received from two to three weeks' treatment between liberation and convalescence.

Meals were served at 8 A.M., 12 NOON, 3.30 P.M., and 7 P.M. Eating-utensils and tables were kept scrupulously clean. The dining-rooms were light, airy, and cheerful. Though mess tins only were at first available, these were superseded as soon as possible by crockery. All this was done as part of a general plan to introduce into the surroundings an atmosphere of civilisation.

CONDITION ON ADMISSION

General Condition.—Despite the treatment they had received before admission nearly all the patients presented the same picture both mentally and physically. Apart from the universal desire for food, and the truly voracious appetite they displayed, they were utterly apathetic, dull, and submissive. They conversed hardly at all between themselves, did not express any emotion, and appeared to have little interest in life. Very few wanted to write letters or communicate in any way with the outside world. A cheerful remark would often be met by a completely vacant stare, and carelessness of dress and habit was the rule. At this stage they were all amenable to the very moderate discipline imposed, and almost no initiative whatsoever was shown. This total lack of interest was particularly noted among those who had been only a short time under medical care.

Great changes, however, were observed after a few days. Meal-times became noisy, often with complaints of insufficient food or of petty thieving. Vast quantities of food were consumed, and, if a meal could not be finished, an attempt would be made to smuggle out the remainder. Initiative returned and was particularly directed to methods of obtaining more food, despite the very large diet. Many showed a highly developed form of cunning in this respect, the most notable effort being the theft of a calf from a neighbouring field. This animal was introduced into the camp and slaughtered, and the patients began to eat the meat raw. When this was stopped, and some scraps of meat were buried, the patients waited until they were free from supervision and then recovered and ate the meat. In the early stages these people could not believe that any meal in the future could be anticipated with confidence. Meanwhile all amenities, such as pianos, indoor games, and literature, were eagerly asked for, a small orchestra was formed, and later on games of football were played.

Physical Condition.—Gross emaciation was usually seen, due both to loss of virtually all subcutaneous fat and to extreme wasting of muscle. The absorption of subcutaneous fat made the skin hang in loose folds, particularly on the buttocks, which came to be recognised as the first site in which generalised wasting of tissue became apparent. In advanced cases the anus became clearly visible between the tubera ischii, and owing to the absorption of the circumanal fat some degree of rectal prolapse was common.

Wasting of muscle was shown in its most striking form in the glutei and in the muscles of the limbs. Usually the loss of tissue was most pronounced in the lower limbs, in the gluteal area, and over the vastus medialis on the inner side of the thighs; in the upper limbs the wasting was seen mainly in the deltoid muscle, the biceps, and the flexors of the forearm. In advanced cases, however, the loss was so great that no real selective action could be observed. Wasting was less well marked in the muscles of the abdominal wall, and the fat over the upper part of the rectus sheath was often retained. In the back the thoracic spinous processes and the scapulæ became unduly prominent. The degree of facial emaciation was not necessarily related to the wasting in other parts.

TABLE I—ANALYSIS OF DIETS

No. of days	Type of diet	Protein (g.)	Fat (g.)	Carbo-hydrate (g.)	Total calories
9	High-fat	330	356	853	8255
3	Additional carbohydrate	263	217	943	6964
12	Relative high-fat (average of foregoing)	313	329	877	7938
10	High-carbohydrate	278	224	1048	7518
22	Over-all average	297	281	956	7747

The skin was often dry, scaly, and covered with sores, many of which had originated from scabies. All hair had been shaved from the patients' bodies.

No gross vitamin deficiencies were observed, and no famine œdema was seen; hence the weights on discharge are not influenced by a pathological increase in fluid.

THE DIET

The extraordinary appetite displayed was first appreciated when bitter complaints about the inadequacy of the diet were made during the first days. At this time the Army 'Compo' ration was in use, having an average value of 3600 calories. It was then resolved that every effort must be made to satisfy the patients' appetites so long as no harmful effects developed. "The danger of stuffing a starving man is notorious" say Hutchison and Mottram (1936), and this principle was kept strongly in mind.

The increase in diet began on May 17 and was continued until June 7, a period of twenty-two days. In addition to food supplied by the Army, further supplies of potatoes were obtained, and dairy produce was requisitioned from local farms. The last source of supply ceased on May 26, when all such produce was ordered by Military Government to be supplied to the medical units handling cases directly out of the concentration camp.

As a result of this order the fat content of the diet was considerably reduced, but this reduction was to some extent compensated by an increase in carbohydrates. There were thus two periods in the investigation in which the average constitution of the diet shows considerable variation. These will be arbitrarily referred to as the high-fat period, from May 17 to May 26, and the high-carbohydrate period, from May 27 to June 7.

Despite the considerable increase in the diet that resulted from these measures, the cry for more food continued almost to the end; but during the latter part of the high-fat period the demand, especially from Russians and Poles, was for more carbohydrate, particularly in the form of bread and potatoes. The average consumption of fat per head of population in normal times by the Russians and Poles is about half that of Germany or Great Britain. The same is true of the Japanese and Italians, for the general level of poverty was such that cereals were a compulsory replacement for fat, which is the most compact form of fuel we possess. Morgulis (1923) remarks that Irish and Bavarian peasants, accustomed to a bulky diet of bread and potatoes, suffer greatly when put on a small quantity of highly nourishing food. Though this agrees with the present findings, he says in the same paragraph that the habitually underfed are much discomforted when given a sufficient diet, and concludes that appetite and subjective feeling are unreliable guides in the matter of nutrition. Experience in the present case did not coincide with these views. Patients certainly appear to have regarded the highest hospital diet, of 3000 calories, as inadequate, since great objection was raised by those readmitted to hospital at the prospect of returning to this scale of diet.

Table I shows the diets and their calorie values. The average value of the diet during the high-fat period was 8255 calories, and during the high-carbohydrate period 7518 calories, whereas the average for the w period was 7747 calories. Though both diets are extre large, they proved to be adequately balanced. fat content in the first period, however, judged by the subjective reaction, was almost certainly higher than necessary. Every effort was made to check the amounts of food used, and every meal was carefully supervised. Measurements of the swill showed that, when about 800 patients were being fed, only about a bucketful a day was going to waste from the meal-tables.

Fig. 1 shows the calorie value of the daily diet and of the protein, fat, and carbohydrate constituents. This cannot be absolutely accurate, because some food was inevitably carried over from day to day in the kitchens. The figures were obtained by making an accurate daily check of all food provided and dividing the total by the number of patients being fed. Allowance was made for the peeling of potatoes.

Typical diets from each of the two periods were as follows:

Items	High fat (oz.)	High carbo-hydrate (oz.)	Items	High fat (oz.)	High carbo-hydrate (oz.)
Fresh meat (with bone)	14	—	Sugar	2 1/2	3
Preserved meat	—	13	Potatoes	42	48
Brown bread	28	36	Tinned vegetables	1 1/4	7
White bread	—	6	Flour	1 3/4	1 1/4
Eggs (8=1 lb.)	4	4	Oatmeal	2	—
Cooking-fat	1/2	1/2	Dried egg	1/2	—
Cheese	3/4	1 3/4	Dehydrated soup	1 1/4	—
Cream cheese	16	—	Cereals (dried)	—	1 3/4
Butter	2 1/2	1 3/4	Bacon	—	1 3/4
Margarine	1 1/2	—	Fresh milk (pints)	1 3/4	1 3/4
Jam	1	1 3/4	Coffee	4/5	—
			Tea	—	1/8

Analysis g.

	High fat	High carbohydrate
Protein	319	295
Fat	400	226
Carbohydrate	763 } 836	984 } 1070
Sugar	73	86
Calories	8442	7669

The daily diet also included salt 1/2 oz., pepper 1/100 oz., mustard 1/100 oz., and two compound vitamin tablets. Seven cigarettes were allowed daily.

An explanation is necessary for the large quantity of cream cheese shown in the high-fat period. This local dairy product was plentiful, and was served on the bread at each of the four meals. Though little was left,

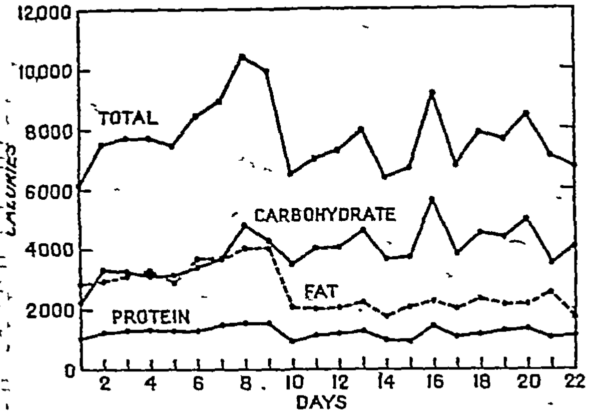

Fig. 1—Calorie values of daily diets and constituents thereof.

omplaints were frequent. The analysis of this item, alculated from standard tables, may be a source of error, ince the fat content of the milk used in its manu-acture was variable. This cheese sours very rapidly, but the free fatty acid, to which the rancid taste is due, s a powerful agent in the promotion of hydrolysis and absorption of fat. This effect, together with the possibly beneficial action of rancid cheese on the intestinal flora, may have caused a disproportionate rise in weight among those patients who consumed their full ration.

The very high calorie value of the diet finds its nearest comparison in a report of Woods and Mansfield (1904) where lumbermen consumed a diet of an average value of 8083 calories daily, containing 164·1 g. of protein, 387·8 g. of fat, and 982·0 g. of carbohydrate. The lumbermen, however, in contrast to our patients, were taking extremely active exercise.

The large diet was very well tolerated. No vomiting and very few cases of lienteric diarrhœa were reported. Certainly at this stage in treatment it seemed perfectly safe to satisfy the subjective desire for food to the utmost. The question arises whether too great precautions were taken in the early stages of treatment when considerably smaller diets were used. Though an initial period of invalid feeding is desirable, particularly to allow the gastro-intestinal tract to recover its function, it appears that this should not be continued, unless there are definite contra-indications to a more substantial diet, for more than a few days at the most. After this the subjective desire for food should be regarded as the safest guide. Though this is contrary to general opinion, Leyton (1946), investigating a very similar field, came to the same conclusion. The great and rapid improvement in both physical well-being and mental health in the vast majority of cases was due largely to the adoption of this principle.

VARIATION IN BODY-WEIGHT

The convalescent camp accommodated patients from May 12 to June 9, during which period 1393 patients were admitted. Of these, 98 were returned to hospital, many going reluctantly. Weight records were kept in 930 of the remaining cases during the diet-observation period (May 17 to June 7) and on June 8, when no record was made of the diet. Thus weight records were made on twenty-three successive days.

In 45 cases weight was either stationary or lost. Of these, 9 were Frenchmen, who were evacuated to a hospital in France by air while still very weak. The weight of the remaining 36 averaged 55·7 kg. Many of these were sent for radiological examination of the chest as possible cases of pulmonary tuberculosis. The congested conditions in the hospitals were such that those who were not definitely shown to be suffering from a demonstrable lesion were returned to the camp. Possibly, however, the lack of gain in weight may have been due to occult tuberculosis.

The weight records of the 885 who did gain weight, however small the gain, were used to ascertain the average weight on admission and the rate of recovery of body-weight.

Average Body-weight.—On admission, the body-weight averaged 54·2 kg. Starling (1930) gives 70·3 kg. as the average weight of an Englishman. If this is taken as a criterion, the average degree of wasting was 23% of the original body-weight. (It is equally true to say that 30% of the starved body-weight must be gained to allow recovery to the original weight.)

Mollison (1946), at Belsen, found that the average weight of 18 men who were strong enough to stand on the scales was 44·0 kg., and that of 11 women 35·3 kg. Some of these had known their weight previously, and in these cases the average loss of original body-weight was 38·8%. From these figures it is deduced that the average male weight before starvation was 71·9 kg.; hence the adoption of Starling's figure appears reasonable.

Rate of Weight Recovery.—This was investigated by taking groups of patients according to periods of observation from two to twenty-three days. Subjects who could not be observed for two days or more were excluded from the series. The percentage gain in starved body-weight per day of observation was calculated in every case, and the average for each observation period was taken. The results have been plotted in fig. 2. The number of subjects for each period of observation is shown in the background to give an index of reliability. From the plotted figures a smooth curve was drawn to indicate the rate of weight recovery. A decrease in this rate corresponding to increased length of the observation period is demonstrated.

Since each figure represents the average gain over the number of days in question, it is clear that this graph does not indicate the rate of recovery in an individual patient. With the use of the smooth curve in fig. 2 this was calculated for the average patient of 54·2 kg. by the following method. The expected gain over two days was plotted. This was subtracted from the expected gain over three days, the difference giving the gain for the third day, which was then also plotted. This total was then deducted from the total anticipated gain over four days, thus giving the actual gain for the fourth day. This procedure was continued to give the curve shown in fig 3. A reduction in the rate of gain is observed after the first week. Thereafter a fairly

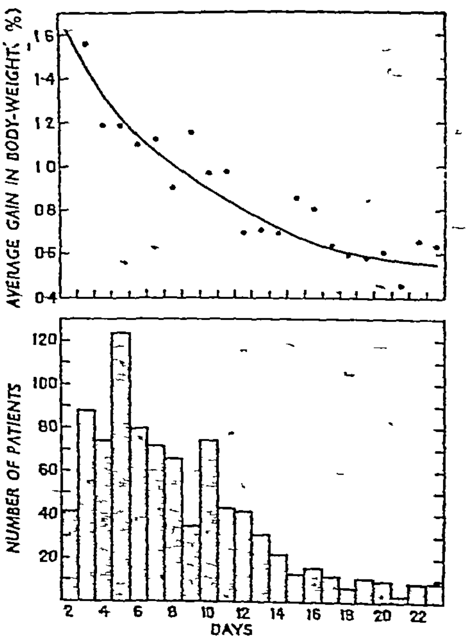

Fig. 2—Speed of weight recovery. Above, average daily gain for each observation period, expressed as percentage of starved body-weight. Below, histograms denoting number of patients in each observation period.

constant, though smaller, rate of gain appears to be maintained.

Examination of this graph of the average patient shows that the weight gained during the first six days is equal to that gained in the following seventeen days, and that 58% of the total gain in weight during the twenty-three days takes place during the first week. If the rate of gain of weight is continued in the way suggested, recovery to the weight of 70·3 kg. might be expected after about seventy-five days.

Effect of Refeeding in Different Weight-groups.—The body-weight records obtained were also used in investigating the effect of refeeding in different weight-groups. The degree of starvation postulated can only be regarded as a mean, since all degrees of starvation were found among the released prisoners. It seemed justifiable to consider the lower weight-groups, despite normal variations, as having been exposed to greater starvation than those in the higher weight-groups. Accordingly the rate of weight recovery among the different categories was investigated. The lightest of these included the few patients whose initial weight was less than 40 kg. and the heaviest those whose weight was more than 70 kg. Between these limits groups were taken at 5 kg. intervals. The results are shown in table II. A striking difference in the rate of weight recovery is observed, the lower weight-groups making a greater rate of gain and over a longer period than the higher groups. It is particularly interesting to compare the average gain per cent. of the original body-weight for each group with the same figure for the whole series for the corresponding time, in each instance, the latter being obtained from the smooth curve in fig. 2.

These results demonstrate clearly that the high diet, demanded by the cry of nature, had definitely beneficial results, rapid response being shown by the gain in weight. This gain is especially pronounced during the first week of high-diet refeeding. Clinical confirmation is found in the absence of ill effects, and in the fact that, at the end of this period of a week, most patients were considered sufficiently well recovered to be discharged.

RELATION OF DIET TO SPEED OF WEIGHT RECOVERY

The size and constitution of the diets and the rate of weight recovery having been examined, an attempt was made to relate the results obtained. It was desirable to ascertain whether greater gains of weight were made during the high-fat period or during the high-carbohydrate period.

TABLE II—WEIGHT GAINS IN DIFFERENT WEIGHT-GROUPS

Weight-group (kg.)	No. of patients	Av. period of observation (days)	Gain in body-weight		Av. daily gain % of body-weight	Av. gain % of body-weight for whole series in same period*
			Actual (kg.)	Percentage of starved body-weight		
Below 40	11	9·5	4·5	12 2	1·28	0·93
40–44·9	52	11·3	6·3	12·4	1·10	0·84
45–49 9	156	8·7	5·0	10·5	1·21	0·97
50–54·9	265	8·7	5·1	9·8	1·13	0·97
55–59 9	217	7·1	4·4	7 7	1·09	1·07
60–64·9	110	7·0	4·3	6 9	0·99	1·08
65–69·9	56	6·9	4·5	6 6	0·96	1·08
Above 70	10	7·3	4·1	5 6	0 77	1·06

* Calculated from fig. 2.

To obtain figures for weight recovery during the high-fat period it was necessary to include patients who had had a further three days on the high-carbohydrate diet.

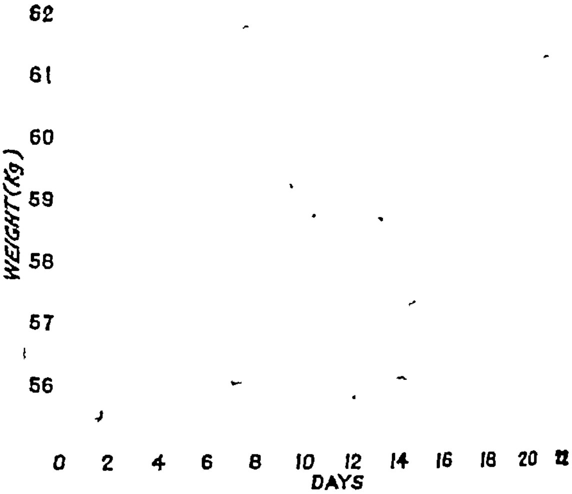

Fig. 3—Average weight of patients during refeeding period.

This was necessary because, when the involuntary ch of type of diet took place, it was impossible to arr accommodation elsewhere for patients who had att the degree of recovery compatible with discharge. The first twelve days of the period, on the first nine of which the high-fat diet had been given, and on the last three of which the high-carbohydrate diet had been given, was therefore taken together as a relative high-fat period.

The diet during this period had an average value of 7938 calories a day; of these, 16·2% were derived from protein, 38·5% from fat, and 45·3% from carbohydrate (table I). Observed for an average of 8·5 days, 18 patients gained at the average rate of 1·07% of body-weight a day. The equivalent for this period in the whole series is 0·98% (fig. 2).

The high-carbohydrate diet had an average value of 7518 calories a day; of these, 15·2% were derived from protein, 27·7% from fat, and 57·1% from carbohydrate. Observed for an average of 5·3 days, 476 patients showed an average gain of 1·19% of body-weight a day. The equivalent for this period in the whole series is 1·20% (fig. 2).

The relative high-fat diet had a calorie value 5·5% greater than the high-carbohydrate diet, and a greater rate of gain with the diet of higher value is observed. This is surprising, because it was not thought possible that these large quantities of food could be fully utilised by the body. It seemed particularly unlikely, even allowing for the abnormal condition of the patients, that the 356 g. of fat fed during the earlier period could be fully absorbed. However, the only real test of fat absorption—analysis of the fæces—could not be carried out under the prevailing conditions.

Almost equally good gains in weight were recorded with a diet poorer in fat and richer in carbohydrate. It is interesting that during the period when more fat was being given in the diet than may have been assimilated the subjective desire was for more carbohydrate.

It is likely that all, or very nearly all, the protein was absorbed to make good the great tissue loss. All the meat in the diet was eaten, like everything else, but this item never became a subject for complaint. Chittende (1907), who advocated a reduction in the protein content of the normal diet, advised a high-protein content in the treatment of malnutrition.

SUMMARY

The convalescent from starvation whose gastro-intestinal tract has begun to recover its function, often shown by the cessation of diarrhœa, and who is not confined to bed, displays a very great desire for food.

The use of a diet of high calorie value to satisfy this appetite seems to be justified.

A study was made of 930 men who had been liberated from German concentration camps and had received initial hospital treatment for two to three weeks. The average degree of wasting at the start of the investigation was estimated to be 23% of the original body-weight.

More than 95% of the patients gained weight quickly, and advanced greatly towards the full recovery of health on rich diets of between 7500 and 8000 calories daily. No untoward effects developed, and it is considered that the optimum constitution of such a diet should be 225 g. of fat, which contributes largely to the recovery of weight; 275 g. of protein, to provide for the regeneration of the wasted tissues; and 1000 g. of carbohydrate.

The results suggest that the greatest benefit from such a diet arose in the first week and was in proportion to the amount of starvation.

Measures to encourage mental rehabilitation are desirable, since, despite the initial complete lack of interest in the surroundings, the mental and moral inertia soon gives way when weight increases. In fact, the patient's interest in his surroundings is a good indication of the degree of recovery.

My thanks are due to all ranks of 3 Field Dressing Station and 49 Field Surgical Unit for their assistance in this investigation; and also to Prof. H. A. Harris and Dr. Ian Murray for their advice and criticism in connexion with the preparation of this paper.

UNIVERSITY OF EDINBURGH

REPORTS by Garcia Lopez et al. (1946) on the treatment of tropical sprue, and by Brody and Gore (1946) and Dalton et al. (1946) on the treatment of cœliac disease, have told of the excellent response that may result from the administration of folic acid. The present report is primarily concerned with the hæmatological changes in 10 cases of the sprue syndrome after treatment with synthetic folic acid. A short account of the effects of treatment on the clinical features and the absorption of fat is also included.

A fat-balance test carried out according to the method of Cooke et al. (1946) was done on all adult patients except cases 2 and 4, where it could not be undertaken for reasons given below. A similar test, in which 50 g. of fat was given daily for 3 days, was done on 17 adult controls and showed a percentage absorption ranging from 91·3% to 98·5%, mean 95·4%. Since no information was available about fat-balance tests in infants, a daily intake of 25 g. of fat was arbitrarily selected. The percentage absorption of fat in normal infants given this amount was found to be the same as in normal adults given 50 g. daily. Before folic acid was tried, all the adult patients had been treated for long periods with a high-protein low-fat diet and parenteral liver without attaining normal blood figures. Special diet and iron had been equally unsuccessful in the hypochromic anæmia of cœliac disease. The hæmatological and clinical findings and the results of the fat-balance tests before and after treatment with synthetic folic acid are given in tables I and II. The hæmoglobinometer used in this investigation gave a reading of 100% at 13·8 g. per 100 ml.

TROPICAL SPRUE

Case 1.—A man, aged 59, first had attacks of diarrhœa while in Sumatra in 1916; sprue was diagnosed in 1932. During the past twelve years he had frequent relapses of diarrhœa with pale frothy stools. In 1933 examination of a stool showed total fæcal fat 52% (split 63%, unsplit 37%), and many fatty crystals. An oral glucose-tolerance test gave an abnormally flattened curve.

The patient developed a psychotic depressive state in 1933 and was admitted to a mental home for treatment. He was discharged in 1934 and was unable to work during the next twelve years.

He was readmitted to a mental hospital in May, 1946, with an exacerbation of depression. Because of the fatty diarrhœa he was transferred to our ward for treatment with folic acid in August, 1946.

On admission he was passing 7 pale frothy loose stools a day. Total fat in dried stool 31·5%; fat-absorption 48·7%. He was extremely depressed, but otherwise his general condition was good. There was histamine-fast achlorhydria. Sternal puncture showed the marrow to be normoblastic, with an increase of early and intermediate normoblasts.

After a control period the patient was given 100 mg. of folic acid intramuscularly, followed by 20 mg. daily intramuscularly from the 2nd to the 21st day of therapy, and then 20 mg. by mouth from the 22nd to 36th day.

The rise in the blood-count was slight and macrocytosis persisted; there was no improvement in fat-absorption; but there was a dramatic and rapid effect on the diarrhœa, a reduction of abdominal distension, and a gain in weight and appetite. The patient's mental state was not improved.

The next case was selected for study for the specific purpose of ascertaining whether folic acid would correct the macrocytic blood picture, which in our experience is not uncommon in the sprue syndrome even when the Hb level is 100% or more, and often does not respond to large amounts of parenteral liver extract.

Case 2.—A man, aged 35, who had been in Egypt in 1935–36, had attacks of diarrhœa, with pale yellow loose stools, from 1943, when he was on service in North Africa. In 1944 he began to feel very weak and developed a sore tongue. He was admitted to a casualty clearing station in Italy in 1945, when his red-cell count was 1,640,000 per c.mm. and Hb 59%: the marrow was megaloblastic. There was no response to injections of liver extract, but the blood-count improved after blood-transfusion and the administration of liquid liver extract by mouth. The patient was evacuated to the United Kingdom still complaining of weakness and flatulence. The stools continued to be pale and loose, and sprue was diagnosed. Injections of liver extract were given during 1945–46.

He was referred to us as an outpatient and not admitted to hospital owing to extreme shortage of beds. At the start of treatment he was having one or two greasy but formed motions daily. His general condition was good. Red-cell count 4,160,000 per c.mm., Hb 100%, colour-index (C.I.) 1·2, mean corpuscular volume (M.C.V.) 103·4 cμ, mean corpuscular hæmoglobin concentration (M.C.H.C.) 32·1%.

Folic acid was given by mouth in a dosage of 20 mg. daily for 30 days. The red cells remained macrocytic despite a slight but definite rise in the blood-count.

Case 3.—A woman, aged 70, developed sprue while in India in 1931. During the past fifteen years she had continuous treatment with special diet, injections of liver extracts, and supplements of vitamins, in different places. During this time she had numerous severe relapses, and her health was never satisfactory.

When she came under our charge she was having 2 or 3 bulky pale motions daily. Total fat in dried stool 37·7%: fat-absorption 71·4%. Her general condition was very poor,

TABLE I—EFFECT OF FOLIC ACID ON CLINICAL STATE AND ON FAT-ABSORPTION

with pellagrinoid skin and a well-marked tendency to bruise and bleed. The marrow was normoblastic.

Folic acid was given by mouth in a dosage of 20 mg. daily for 30 days. The macrocytic anæmia was unchanged, but fat-absorption improved, and there was a rapid and dramatic improvement in the frequency and character of the stools, and in the patient's feeling of well-being. After she left hospital she ceased taking folic acid and had a severe clinical relapse without any change in the blood-count.

Case 4.—A woman, aged 59, lived in India in 1916–20, during which period she had one brief attack of diarrhœa, with pale stools. She had no looseness of the bowels after leaving India until July, 1946, when diarrhœa began again. Thereafter she often had 6 or 7 loose frothy pale stools daily. She also had heartburn, flatulence, and bouts of vomiting, and lost $1\frac{1}{2}$ st. in weight in six months. Sprue was diagnosed, and she was treated with diet and parenteral liver without improvement.

In view of the long time which elapsed between the patient's leaving India and the development of steatorrhœa in Great Britain, it is debatable whether she was a case of tropical sprue or of idiopathic steatorrhœa.

In 1947 she was seen in a private nursing-home, where intensive investigations were impracticable. Free hydrochloric acid was present in her gastric juice, and the fat content of a dried specimen of stool was 34%. Red-cell count 3,480,000 per c.mm., Hb 80%, C.I. 1·1. Folic acid was given by mouth in a dosage of 20 mg. daily for 21 days.

The macrocytic anæmia was not improved, but there was a rapid improvement in the patient's general condition indicated by a better appetite, loss of the abdominal distension, and control of the diarrhœa.

IDIOPATHIC STEATORRHŒA

Case 5.—A woman, aged 37, was admitted to hospital with fatty diarrhœa and megaloblastic anæmia refractory to injections of a potent liver extract.

At the start of folic-acid therapy the total fat in the dried stool was 25·4%, and fat-absorption 76·0%. The patient was having 3 or 4 pale loose stools daily, and her general condition was poor. A test-meal showed free hydrochloric acid. The bone-marrow was megaloblastic. The red-cell count was 1,370,000 per c.mm., Hb 40%, C.I. 1·5, white cells 7800 per c.mm., packed cell volume 19%, M.C.V. 138·7 c.μ., M.C.H.C. 28·9%, reticulocytes 3·5%

Folic acid was given by mouth in a dosage of 20 mg. daily for 10 days, and thereafter 10 mg. daily for 19 days.

The reticulocyte-count began to rise on the 4th day, reaching a peak of 38·6% on the 6th day. On the 29th day the red-cell count was 3,590,000 per c.mm., Hb 72%. This rise was considered highly satisfactory and fully up to the standard obtained in a classical case of pernicious anæmia with an equivalent initial erythrocyte-count treated with parenteral liver extract. Coincidentally with the blood changes her clinical state improved remarkably.

Continuation of folic-acid therapy for another 19 days, however, did not increase the number of red cells. Accordingly it was given for a further 17 days and supplemented by three injections of 4 c.cm. of 'Anahæmin.' This also did not improve the blood findings, the red-cell count on the 65th day of treatment being 3,680,000 per c.mm. while the blood picture remained macrocytic. Treatment with proteolysed liver ('Hepamino') was then begun, and this resulted in a rise of 1,000,000 red cells per c.mm. in 14 days, and the restoration of the M.C.V. to normal.

The hæmatological results of treatment with folic acid in this case must be assessed as unsatisfactory despite the excellent initial response, since the blood picture was not restored qualitatively or quantitatively to normal. There was no improvement in fat-absorption, but a rapid and dramatic improvement in the diarrhœa and the patient's general health.

Case 6.—A man, aged 50, had been under our care with fatty diarrhœa for $4\frac{1}{4}$ years before the present admission to hospital, the number of stools commonly being 8–10 daily, sometimes watery, sometimes pale and bulky.

He had had a severe dermatitis of hands, feet, and face for over two years, and this had resisted all forms of therapy. He had been unable to work for over a year because of general weakness.

On admission he had 1 or 2 formed motions daily; total fat in dried stool 32·6%; fat-absorption 75·7%.

A test-meal showed free hydrochloric acid. On three occasions the marrow was found to be preponderantly normoblastic, though an occasional megaloblast was also present. He had a moderate degree of macrocytic anæmia which was entirely resistant to parenteral liver therapy.

The patient was given folic acid by mouth in a dosage of 20 mg. daily for 28 days.

The red cells increased by 1,080,000 per c.mm. in 28 days, and the M.C.V. was restored to the upper limits of normal. Fat-absorption was unchanged. Clinical improvement was definite, and most remarkable of all was the coincident alleviation of the dermatitis, which had almost completely disappeared at the end of treatment with folic acid.

Case 7.—A man, aged 69, served in the Regular Army from 1896 to 1920, and was in India in 1901–06, where he had an attack of acute bacillary dysentery but no other diarrhœal disease. In 1914, when in this country, he developed diarrhœa with loose pale stools. Since then he had frequent exacerbations of these symptoms, sometimes associated with sore tongue. He was admitted to hospital in 1940 with a megalolastic anæmia, and pernicious anæmia was diagnosed. Treatment with potent preparations of liver extract did not restore the blood to normal. During the next 4 years diarrhœa recurred at intervals. Since his general condition was poor he was readmitted to hospital in 1944 for further investigation. Free hydrochloric acid was found in the gastric juice, and the fat-content of the dried stool was 35%. Steatorrhœa was diagnosed. Whether the case should be classified as tropical sprue or idiopathic steatorrhœa is debatable.

Since 1944 the patient has been under observation and has continued to have loose pale stools, usually 2 a day, but more during exacerbations.

He was again admitted to hospital in January, 1947, when folic-acid therapy was begun. At this time he was having 2 or 3 pale loose very bulky motions daily.

On admission the fat in the dried stool was 34·5%; fat-absorption 78·3%. There was considerable œdema of the ankles, and his general condition was poor. Sternal puncture showed a predominantly normoblastic marrow with many early and intermediate normoblasts.

After a control period the patient was given 20 mg. of folic acid daily by mouth. His general condition improved rapidly, and a free diuresis (6600 c.cm. in 48 hr.), associated with disappearance of œdema and with loss of weight, occurred on the 6th and 7th days of treatment. A gain of about 900,000 red cells per c.mm. and 24% Hb took place in 16 days. Despite continued treatment with folic acid for a further 10 days the blood level remained about stationary and the blood picture macrocytic. There was no change in fat-absorption, but there was a rapid and dramatic improvement in the frequency and character of the stools and in the patient's general feeling of well-being.

CŒLIAC DISEASE

Case 8.—A girl, aged 3 years 3 months. At the age of 2 years steatorrhœa began, followed by progressive loss in weight and deterioration in health. On Oct. 29, 1945, the red-cell count was 4,000,000 per c.mm., Hb 65%, C.I. 0·81. Treatment with diet, liver injections, iron, and vitamins A, C, and D led to a steady improvement. Six months later there was a severe relapse which was attributed to discontinuation of dietetic restrictions. The patient was readmitted to hospital in very poor health with the clinical picture of cœliac disease. A moderate hypochromic anæmia was present (table II). Sternal puncture revealed a normoblastic marrow. At the start of folic-acid therapy the patient was passing 2–4 pale bulky stools daily; total fat in dried fæces 32·8%; fat-absorption 69·6%, compared with 95·2% in a control infant of the same age.

She was given 10 mg. of folic acid by mouth daily for 18 days. The blood-count and clinical condition were unchanged, so the dose of folic acid was increased to 20 mg. daily for the next 14 days, again with no improvement.

In view of the low colour-index a further 21 days' treatment with folic acid was given and supplemented with ferrous sulphate gr. 3 daily. At the end of 53 days' treatment with folic acid, the hæmoglobin level was lower than it had been before treatment. Moreover a clinical relapse started about the 40th day of the treatment which was sufficiently severe to prevent the fat-balance test being repeated.

The hæmatological and clinical results of treatment with folic acid in this case were entirely unsatisfactory (tables I and II).

Case 9.—A boy, aged 1 year 10 months, who first suffered from vomiting, followed by diarrhœa, at the age of 13 months. He was admitted to hospital severely ill, and cœliac disease was diagnosed. Treatment with a low-fat diet, iron, and vitamins led to some improvement. Six months later, however, he was still grossly emaciated, weighing about 15 lb. He vomited often and passed many pale frothy stools daily. It was impossible to carry out a fat-balance test because he could tolerate only traces of fat in the diet.

When folic-acid therapy was started he was passing 2–4 pale fatty stools daily. The anæmia was hypochromic and moderately severe.

Treatment with folic acid began with 10 mg. daily by mouth; but the blood-count was unaltered after 12 days so the dose was increased to 20 mg. daily for 18 days, and was continued for a further 17 days at 10 mg. daily.

After 47 days' treatment with folic acid, supplemented during the last 22 days by ferrous sulphate gr. $1\frac{1}{2}$ daily, the red-cell count was lower than when treatment started. The Hb level remained unchanged. There was no change in the appearance or frequency of the stools and no significant gain in weight or reduction in abdominal distension, but the infant showed some general subjective improvement and began to take an interest in his surroundings.

The hæmatological and clinical response to folic acid was unsatisfactory.

TABLE II—EFFECT OF FOLIC ACID ON ANÆMIA ASSOCIATED WITH THE SPRUE SYNDROME

§ 26th ,, ,, ,, ,, ,,

Case 10.—A girl, aged 17 years, who had had cœliac disease since the age of 2 years. On admission, in May, 1946, she had well-marked rachitic deformities; her height was 62½ in. and her weight 5 st. 7½ lb. Red-cell count 1,800,000 per c.mm., Hb 30%. The bone-marrow was normoblastic. She was treated with blood-transfusion, proteolysed liver, a low-fat diet, and vitamin supplements, and was discharged from hospital with a red-cell count of 3,650,000 per c.mm., Hb 70%. She was readmitted to hospital on July 23, 1946, for the purpose of determining the effect of folic acid on the absorption of fat and on the anæmia. The blood-count had been stationary for several weeks before the start of folic-acid therapy. Folic acid was given for 20 days, the daily dose being 20 mg. by mouth. This treatment was ineffective in improving significantly the blood-count or the capacity to absorb fat.

DISCUSSION

Clinical Effects

Table I clearly indicates that folic acid is a reliable therapeutic agent for the alleviation of certain clinical features of the sprue syndrome in adults. Excluding case 2, who was selected for a particular hæmatological study and whose general condition was satisfactory in other respects, the other adult patients (cases 1, 3, 4, 5, 6, and 7) all showed an excellent clinical response. Diarrhœa was completely controlled within a few days of starting treatment, and the patients all noted a rapid improvement in appetite and sense of well-being.

In contrast to these satisfactory clinical effects in adults are the unsatisfactory results in the patients with cœliac disease (cases 8, 9, and 10). We were particularly disappointed with these findings in view of the excellent results published by Dalton et al. (1946). Their two cases of cœliac disease had a megaloblastic bone-marrow, a finding which is exceptional in cœliac disease and whose significance is discussed below.

Fat-balance Test

Fat-balance tests were carried out before treatment with folic acid in 7 out of the 10 cases recorded in table I. In all cases the test showed a failure of fat-absorption as compared with controls. In 6 cases the test was repeated after treatment with folic acid had been completed. Only in case 3 did treatment improve fat-absorption as assessed by this test. There appeared to be no correlation between improvement or lack of improvement in fat-balance tests and improvement or lack of improvement in the clinical or hæmatological results of treatment. Thus cases 1 and 5 showed dramatic clinical improvement and cases 5 and 6 showed an excellent initial or terminal hæmatological response, and yet their percentage absorption of fat was unaltered. Though the diagnostic value of this test is undoubted, its prognostic value is still uncertain.

Hæmatological Aspects

The published reports show that a macrocytic anæmia is often present in tropical sprue and idiopathic steatorrhœa, whereas in cœliac disease a hypochromic anæmia is more common. Since most of the reports were published before the introduction of sternal puncture as a routine diagnostic procedure, the proportion of patients with genuine megaloblastic blood formation cannot be assessed. There appears, however, to be sufficient evidence to show that when a severe anæmia—i.e., an erythrocyte count below 2,000,000 per c.mm.—is found in adults with the sprue syndrome, not only is the blood picture macrocytic but the bone-marrow is generally megaloblastic. This also appears to be true of some patients with cœliac disease.

During the past year we have investigated 33 adults with the sprue syndrome. The anæmia was usually only moderate (mean red-cell count about 4,000,000 per c.mm.). The blood picture was usually macrocytic, as judged by the stained film, the high colour-index, and the high M.C.V.; and the bone-marrow was normoblastic. The macrocytosis was presumably determined by the increased numbers of early and intermediate normo present. These patients had received treatment high-protein low-fat diets, supplemented with injections and vitamins, for months or years before saw them.

The degree of macrocytosis which may be present the sprue syndrome when the red-cell count is 4,000, 5,000,000 is an interesting and striking feature which rarely seen in our experience in cases of classical cious anæmia with similar blood-counts who have received adequate liver therapy. We have found the anæmia associated with the sprue syndrome to be particularly resistant to all forms of treatment, including the injection of both purified and crude liver ex and the administration of iron and vitamins. Our that folic acid might supply the answer to this t peutic problem does not appear to have been f judged by the unsatisfactory hæmatological resp obtained in 9 out of 10 patients reported in this p Accordingly we suggest that, since neither paren liver extract nor folic acid may be effective in rest the blood picture to normal, some other hæmatinic f as yet unidentified, is required. That this factor may present in liver is suggested by our findings in case in which a rise of 1,000,000 per c.mm. in the red-cell co followed 14 days' treatment with proteolysed liver (hepamino) after the count had been stationary for 37 days on folic acid.

The unsatisfactory hæmatological responses which we report are in striking contrast to the results obtained by Spies et al. (1946) and by Garcia Lopez et al. (1946) in cases of tropical sprue in Cuba. These workers laid down definite criteria for the selection of patients, one of which was that the marrow should be megaloblastic. Only one of our patients had a classical megaloblastic marrow at the start of folic-acid therapy, and it was in this case that we obtained the most dramatic initial hæmatological response. Cases 6 and 7 both had typical megaloblastic marrows when we first saw them several years before the present investigation. The bone-marrow immediately before the start of folic-acid therapy was mainly normoblastic but contained many nucleated red cells intermediate in appearance between megaloblasts and normoblasts. We attributed this appearance to the preceding course of injections of liver extract, which had produced a partial maturation of the megaloblast series without restoring the blood-count to normal. In cases 6 and 7 folic acid completed the transformation to normoblastic blood formation and produced a rise in the blood-count of about 1,000,000 red cells per c.mm.

The Cuban series included only cases with an initial red-cell count of less than 2,500,000 per c.mm., whereas the red-cell count in our series at the start of folic-acid treatment was, with one exception, about the same as that recorded by Garcia Lopez et al. (1946) at the end of folic-acid therapy. The mean red-cell count at the end of treatment with synthetic folic acid in the 18 cases of tropical sprue recorded by Garcia Lopez et al. was 4,073,000 per c.mm.; whereas in a random series of 13 cases of tropical sprue and 20 cases of idiopathic steatorrhœa seen by us the mean red-cell counts after treatment with diet, liver injections, and vitamins, but without the administration of folic acid or proteolysed liver, were 4,162,000 and 3,912,000 per c.mm., respectively. These mean figures are not significantly different from that of the Cuban series ($t = 0{\cdot}36$, $P = 0{\cdot}75$; and $t = 0{\cdot}79$, $P = 0{\cdot}43$, respectively).

Another point noted by Garcia Lopez et al. (1946) was that their patients had eaten for long periods a diet deficient in essential food factors, particularly first-class protein and the vitamin-B complex, and that infection and infestation of the alimentary tract was commonly present. In contrast, no evidence was obtained that our patients had been taking an unsatisfactory diet before the onset of the sprue syndrome, and after the diagnosis had been made and before the start of folic-acid therapy they had been given for months or years a high-protein diet with supplements of vitamins.

In other words, the patients in the Cuban series appeared to be suffering from both a direct and a conditioned nutritional deficiency, whereas in our patients the deficiency was solely conditioned by a failure in absorption or utilisation. Accordingly it is doubtful whether the cases of the sprue syndrome reported by Garcia Lopez et al. should not be classified as examples of primary nutritional macrocytic anæmia, and whether dietary deficiency, supplemented by infection or infestation of the alimentary tract, had not led to intestinal changes causing diarrhœa and steatorrhœa. A vicious circle would thus be created leading to superimposition of a conditioned dietary deficiency on a direct dietary deficiency. One of us (R. H. G.) has seen many cases of severe malnutrition and anæmia in Indian troops stationed east of the Brahmaputra river in India and Burma. These men had suffered from many years of malnutrition before joining the Army, and during the jungle fighting, where supply difficulties were extreme, they suffered from diarrhœa, sometimes watery, sometimes fatty; avitaminosis, chiefly of the B complex; and anæmia, which was sometimes normoblastic but was frankly megaloblastic when anæmia was severe.

In idiopathic steatorrhœa and cœliac disease in this country, we suggest that the steatorrhœa is not primarily due to dietary deficiency or infection but results from an abnormality of the bowel, genetic (constitutional) in origin and leading to jejuno-ileal insufficiency and steatorrhœa. In keeping with this hypothesis is our finding of a familial history of steatorrhœa in some of our patients, the most striking example being a family in which five members have the syndrome.

If the abnormality of the intestinal tract is a genetic character, how is it that the syndrome displays itself sometimes in infancy and sometimes not until adult life? It is possible that, associated with the gene(s) primarily responsible for the condition, there are modifying genes and special environmental factors—e.g., infection of the alimentary tract, dietetic indiscretions or deficiencies, climatic variables, and unaccustomed and excessive physical effort—which so influence the action of the principal gene(s) that in some instances the syndrome is expressed in the infant as cœliac disease, whereas in others it appears only in the adult.

That these suggestions are not unreasonable is indicated by a consideration of the closely allied condition, Addisonian pernicious anæmia. It is widely accepted that the primary cause of this disease is an abnormality of the stomach, genetic in origin, leading to achlorhydria and, with advancing years, to a failure in production of intrinsic factor and finally to a megaloblastic anæmia.

If this hypothesis is true, it is not surprising that the results of folic-acid therapy in idiopathic steatorrhœa and cœliac disease in this country may be far less striking than those obtained in patients with the sprue syndrome in whom long-continued pre-existing dietary deficiency and intestinal infection and infestation are significant features.

Though there is good reason to believe that folic acid will give dramatic results in the treatment of megaloblastic anæmia in the sprue syndrome, there is little published evidence to show that folic acid alone will invariably restore the red cells qualitatively and quantitatively to complete normality. In the 18 cases recorded by Garcia Lopez et al. (1946) 15 were given folic acid for periods ranging from 60 to 152 days. Of these only 4 attained a red-cell count of 4,500,000 per c.mm., and none reached a level of 5,000,000 per c.mm.

It may be that, after the marrow has changed from megaloblastic to normoblastic as a result of folic-acid therapy, some other missing factor is required to enable the erythropoietic mechanism to function normally.

SUMMARY

Folic acid was given to 10 patients with the sprue syndrome. In 9 cases the hæmatological response was considered unsatisfactory, in that this treatment either produced no significant rise in the red-cell count or failed to restore the blood-level and hæmatological picture to normal.

Diarrhœa was controlled and clinical improvement resulted in the 7 adults suffering from tropical sprue or idiopathic steatorrhœa. In contrast, no significant benefit was observed in the 3 patients with cœliac disease.

Folic acid did not improve fat-absorption, as estimated by fat-balance tests, in 5 out of 6 cases of the sprue syndrome.

Our results are compared with those of other workers.

We are indebted to Messrs. Lederle & Co. Inc. for supplies of folic acid, and to Prof. R. W. B. Ellis and Prof. L. J. Davis for permission to include in this report patients under their charge.

CARE OF THE URINARY TRACT IN PARAPLEGIC PATIENTS

REVIEW OF 82 CASES

HUGH DONOVAN
M.B. Birm., F.R.C.S.
SURGEON TO THE BIRMINGHAM UNITED HOSPITAL

THE experience gained in the treatment of 82 paraplegic soldiers in the Midland Regional Spinal Unit is here reviewed.

Almost all the men arrived with a suprapubic cystotomy of the high type—i.e., a fistula about 5 cm. above the pubis. In two patients this leaked, especially when the man lay on his face. The cause of the relaxed wound was evidently the poor condition of the patient, and possibly there was also a trophic element. Improvement in general health led in all cases to healing of the fistula round the tube and cessation of leakage.

BLADDER DRAINAGE

Since phosphatic incrustations were liable to form on the tube head, we changed the tube at weekly intervals. The Malecôt type was preferred to the de Pezzer, as being easier to withdraw and giving better drainage. We took special care to prevent the tube from playing in and out of the bladder, because this must carry in infection and probably damages the trigonal region. Too small a tube is easily blocked—a serious accident, often leading to ascending pyelitis. Size 28 Charrière was our standard. Some care is needed in reintroducing the tube, and the direction of the track must first be ascertained in each case. On one occasion the tube was pushed into the peritoneal cavity instead of into the bladder; fortunately the disaster was retrieved. We now teach ambulatory patients to care for their suprapubic apparatus and to wash out their bladders. We tried the Millin type of drainage bag, but the slightly greater pressure needed was too much for the paralysed bladder, and we had to go back to the leg bag.

Tidal Drainage

This was begun enthusiastically. Home-made apparatus of various kinds gave way rapidly to the Wells's type; and when, after some months, we received about a dozen of these, mounted on stands, we hoped that our difficulties were on the way to solution. But eventually we decided, not only that the urines were more cloudy, but also that pyrexial attacks were probably commoner with all methods of bladder drainage other than the direct simple one of leading the suprapubic tube into a bedside bottle. With regret, and after extensive trial, we gave up a double-channelled suprapubic tube which allowed continuous-drip irrigation of the bladder, because the exit channel was apt to become blocked.

While tidal drainage or continuous irrigation was the routine we tried many different lotions. The naked-eye appearance of the effluent mixture of urine and lotion seemed to be a reasonable guide to their effect. After trying proflavine (in various dilutions), potassium permanganate, 'Surfen,' and "solution G," we preferred the last; but more recently, for routine bladder lavage four times a day, we have been using 1 in 5000 neutral proflavine.

URINARY ANTISEPTICS

The flora of the drained bladder seems singularly constant. Again and again the laboratory report was *Bact. coli*, *Strep. fæcalis*, *B. proteus*, and *Ps. pyocyanea.*

We have taken reports on the urine of 19 patients at Barnsley Hall and 4 in the Queen Elizabeth Hospital for review. At Barnsley Hall *B. proteus* was reported present 34 times, *Ps. pyocyanea* 58 times, *Bact. coli* 137 times, non-hæmolytic streptococci 71 times, and other organisms twice. At the Queen Elizabeth Hospital *Bact. coli* was reported 19 times, *Ps. pyocyanea* 9 times, *B. proteus* 5 times, enterococci 4 times, staphylococci 4 times, non-hæmolytic streptococci 6 times, and various other organisms, such as monilia and diphtheroids, occasionally. Again it was usual for three or four organisms to be present together; and when the four common organisms were entrenched in the bladder they seemed rarely to disappear; occasionally one or other would not be reported for a few tests, but would reappear later.

It is noteworthy that some organisms do not flourish, and that the flora remains so constant and restricted.

Some ureters were catheterised, and there are records of 7 cases: *Bact. coli* was present alone in 5, in 6 it was present with other organisms; and the 7th was sterile. This finding supports the known invasive property of this organism in the urinary tract. *Strep. fæcalis* is probably not highly pathogenic, and perhaps the same can be said of *Ps. pyocyanea.*

We began with the administration of a sulphonamide in small doses (0·5 g. t.d.s.), and were disappointed to find pyrexial attacks extremely frequent. As emerged later, the organisms, including the varieties of *Bact. coli*, were insensitive to sulphonamides when tested in the laboratory. Since we suspected that the small doses used routinely would allow an insensitive strain to survive, we made a practice of changing to another sulphonamide if a pyrexial attack developed; but even so, the results were disappointing. Mandelic acid also proved unsatisfactory; it did not seem to control pyrexial attacks, and it tended to upset the stomach. The soil matters more than the seed, and, in the treatment of the spinal patient, fresh air, blood-transfusions, and tasty food are of supreme importance.

Finally, we formed the following opinions:

(1) Penicillin was by far the most successful substance for ending a pyrexial attack.

(2) Ammonium chloride, grains 15 four times a day in capsules, was the best routine urinary antiseptic, the pH of the urine being repeatedly checked and kept in the region of 5.

(3) For unexplained pyrexia lasting more than three or four days it was well to carry out pyelography, or else cystoscopy, with an injection of indigo-carmine, so that an obstructed upper urinary tract could be excluded. Where excretion of indigo-carmine was delayed, or there was evidence of dilatation of the ureter in the intravenous pyelogram, we inserted an indwelling catheter into the affected ureter, unless a stone shadow was revealed, in which case we undertook ureterolithotomy.

PYREXIAL ATTACKS

Bouts of pyrexia were common, especially in the ear months. The first problem was diagnosis, for bed were almost constant, and sometimes there were o wounds or incidental diseases, such as diphth infective jaundice, or pulmonary tuberculosis. Often in the absence of clear evidence it was necessary to presume the presence of pyelonephritis.

The urine from the bladder was always infected but sometimes almost clear to the naked eye. The kidneys were rarely, if ever, tender unless obstructed or the site of gross cortical or perinephric abscess. Indeed, since surgical intervention was not indicated except for these complications, we came to regard the absence of spontaneous pain and of tenderness as a strong reason for persisting in medical treatment. This last conclusion was not reached at first, because a patient injured abo the level of the D10 might be expected to have an insensitive kidney and perhaps an insensitive kidney bed. It is usually held that the sensory innervation of kidney is from D10–D12. One patient (sensory level D[illegible] complained of deep-seated pain below the right costal margin, and on investigation nothing abnormal was found except dilatation of the right kidney pelvis and ureter. *In this kidney stone was detected some months* later. In another patient (sensory level D10) the left kidney became tender when a perinephric abscess formed.

In spite of these two clinical observations we did not rely solely on the abovementioned rule but also sought to exclude an obstructed infected kidney by either excretory urography or cystoscopy with injection of indigo-carmine. We did not often find that a presumed pyelonephritis led to delay in the excretion of indigo-carmine; nor did we find, as some writers have maintained, that in such cases the ureter was always dilated. We usually made one or other of these investigations if pyrexial attacks did not respond to medical treatment.

CLOSURE OF THE BLADDER

Writers on the care of the bladder in the paralysed patient, at any rate immediately before the 1914–18 war, did not sufficiently emphasise how easy and desirable it is to close the bladder in the paraplegic patient. The sensation he has when the bladder is full may not be the normal sense of bladder distension—it may be only a tight feeling in the lower abdomen—but it may be sufficient to warn him that *micturition is imminent.* It evidently ascends in the sympathetic cord, and these afferent impressions are said to enter the cord as high as D6. One patient, injured in the region of D3, whose cord is grossly damaged, nevertheless has sufficient warning of impending micturition to be able to catch his urine in a vessel and to keep dry. Thus a patient with an intact micturition centre in the cord can often develop satisfactory automatic micturition with sufficient warning to enable him, in suitable circumstances, to dispense with an incontinence apparatus. The result of closure is that the urine becomes much cleaner to the naked eye, and its flora usually becomes simplified, indeed in many cases only a single organism persisting—e.g., *Bact. coli* or (as in one of our cases) *Ps. pyocyanea.* It may be possible to eradicate *infection completely*, but in the single case in which this was achieved in an automatic bladder, relapse followed. Once the bladder has been satisfactorily closed, pyrexial attacks may cease, and the man's morale is greatly improved; in fact, this type of automatic micturition should be established whenever possible. On the other hand, if a patient is completely bedridden—for example, as a result of a *low cervical lesion*—he may be easier to nurse *with a suprapubic* tube, especially if he has no bladder sensation. In women, too, it may be better to retain the suprapubic tube, though my experience of such cases is not very great. There does not seem, however, to be the same urgency to drain the paraplegic female suprapubically; the short urethra is not liable to slough, and she is spared the danger of epididymitis. Cystoscopy of one or two such cases after several weeks' drainage did not reveal any untoward changes at the bladder-neck or the trigone.

When deciding whether the patient can achieve automatic micturition we have found the following signs helpful:

(1) Does he pass urine during bladder lavage or when the suprapubic tube is temporarily obstructed?

(2) Does he pass urine and empty the bladder during cystometrogram studies at any reasonably low pressure?

(3) Do the muscles in the legs respond to faradism? (At one point we tried to study the faradic response of the bulbocavernosus muscle, but it is a difficult and unsatisfactory muscle to stimulate electrically, and so we have been content to assess the faradic response of the muscles of the legs and feet.)

An unexplained and unexpected finding has been that in some patients wounded comparatively high—e.g., D6—whose leg reflexes have been absent from the beginning, there is no faradic response in the lower limbs. Probably in no case of this type have we succeeded in establishing automatic micturition; and, since voluntary control of the abdominal muscles has gone, it is clearly impossible to empty the bladder by straining.

In the patient whose cauda equina is injured, we have, as Watkins (1936) pointed out, an entirely different problem. Some of these patients can keep fairly dry and empty or partly empty the bladder by regular voluntary straining; no doubt residual urine is often or always present. In such cases we have found that considerable leakage of urine is likely, and that in every case the ureters are somewhat dilated. This is bound to harm the patient, and in one case was associated with deterioration of health and with pyrexia; hence we have thought it wise to defer closure of the bladder during the first two years of the man's paralysis, lest any recovery in the nervous system might be hindered by this depression of his vitality. Some patients have come under our care whose bladders have already been closed, or have never been drained, and it was in these that a dilated upper urinary tract was constantly found.

One patient with a cauda-equina injury (L5) raised special problems.

He came under our care because he appeared to suffer intense pain from his suprapubic tube, especially when he bent to a sitting position. His bladder was so much contracted that, when we tried to obtain a cystometrogram, the radio-opaque medium ran straight up his ureters after only a few cubic centimetres had been introduced into his bladder. Adequate cystoscopic study of the bladder was almost impossible.

It seemed likely that at some stage he had had severe infection, with sloughing of the bladder. After discussion with him we decided to attempt to punch away the region of his external sphincter, so that he would drain constantly through his penis into an apparatus. This was done, and the low pressure afterwards required to run lotion from the urethra into the bladder proved that the obstruction was removed. His bladder was then closed, and remained closed for three months; but unfortunately the obstruction at the urethra seemed to return, he became pyrexial, his previously dilated ureters dilated still further, and eventually his suprapubic wound burst open again.

This case is related because, though the treatment failed, its underlying plan may be correct: with a cauda-equina bladder the proper course may be to remove permanently the obstruction to urination in the region of the triangular ligament, and to allow the penis to drain into a urinal. Later it may be possible to restore some type of voluntary control by one of the well-known methods (using the gracilis muscle or a fascial sling from the rectus muscle). We hope to be able to explore this method further.

Watkins (1936) has suggested that the obstruction in these cases is due to some natural elasticity of the triangular ligament. Certainly it is unlikely to be due to innate tone in the external sphincter, for this has a somatic supply akin to that supplying the external sphincter ani, which in these cases is relaxed and patulous. Nor is the obstruction valvular, for the same pressure (60–90 cm. of water) is needed to force it from whichever direction the attempt is made—from the bladder via the suprapubic tube or down the urethra. Finally, there is no reason to suppose that any elastic or fibrous tissue presses on the urethra at this spot. The problem remains unsolved, but it is hard to escape the conclusion that there is considerable tone in the external urethral sphincter.

STONE FORMATION

Stones formed in 24 patients. In 6 of these the calculus was vesical; in 2, calculi of bladder and upper urinary tract were present together; in 14, stones formed in the upper urinary tract alone.

We recognised from the beginning the importance of preventing stone formation, and the renal tract was always radiographed every two months. Instructions about fluid intake became more explicit as time went on, and soon an intake-and-output chart was kept for all patients. They coöperated well, and the average output is now about 130 oz. per man per day. An extra ration of tea was provided, and beer, too, helped. The position of patients was changed frequently. Lying prone for long periods, in the treatment of sacral bedsores, did not seem to predispose to stone formation.

We tried in all patients to secure a urine of pH 5–5·5. For this purpose ammonium chloride gr. 15 was given in a capsule or chocolate-coated tablet four times a day, and in addition in most cases a high-acid-ash diet was ordered. As a rule the suprapubic tube was changed weekly, because it quickly becomes encrusted—often after even this short period. A straight suprapubic tube seems less likely to become encrusted than a self-retaining one.

In one case vesical calculi formed in spite of tidal drainage with solution G, and in several cases they did not dissolve when the solution was used for six weeks. Only in one case, in fact, did it cause stones to dissolve, and these were small—1–2 cm. in diameter. Of the others, the stone was crushed in 5, evacuated through a cannula in 1, and was left alone in 1; this last patient died of renal sepsis and had calculi in both kidneys. Stones have not recurred in any of our cases after litholapaxy.

Vesical calculi are becoming rarer: presumably the routine care given is proving effective. Two cases which came under our care recently were on tidal drainage for many months up to the crushing of the stone, and this may have actually helped the formation of the calculi, which are presumably less likely to develop in the constantly empty bladder. No special flora seems to be associated with the formation of stone.

The stones were easy to crush, and the suprapubic fistula was not inconvenient, for the expanded end of the self-retaining catheter readily occluded the sinus and allowed the bladder to be distended. The only complication was a long pyrexial attack in one patient, in whom the intravenous pyelogram after the litholapaxy showed widely dilated ureters and kidney pelves; in a few months these contracted to normal. It seemed probable that the vigorous compression of the evacuator dilated the ureters, and in later cases the bulb was compressed very slowly and gently.

Renal and Ureteric Calculi

In 16 cases renal or ureteric calculi were found. In 7, renal calculi developed while the patients were under our care, but in the last year we have found renal calculi in only 3 patients. In 1 of these the stone may have been present before admission; in another it formed while the patient was undergoing orthopædic treatment in another ward.

There is no apparent connexion between stone formation and the level of the paralysis. A stone developed in a dozen of these, mounted on stands, we hoped that our difficulties were on the way to solution. But eventually we decided, not only that the urines were more cloudy, but also that pyrexial attacks were probably commoner with all methods of bladder drainage other than the direct simple one of leading the suprapubic tube into a bedside bottle. With regret, and after extensive trial, we gave up a double-channelled suprapubic tube which allowed continuous-drip irrigation of the bladder, because the exit channel was apt to become blocked.

While tidal drainage or continuous irrigation was the routine we tried many different lotions. The naked-eye appearance of the effluent mixture of urine and lotion seemed to be a reasonable guide to their effect. After trying proflavine (in various dilutions), potassium permanganate, 'Surfen,' and "solution G," we preferred the last; but more recently, for routine bladder lavage four times a day, we have been using 1 in 5000 neutral proflavine.

URINARY ANTISEPTICS

The flora of the drained bladder seems singularly constant. Again and again the laboratory report was *Bact. coli, Strep. fæcalis, B. proteus*, and *Ps. pyocyanea.*

We have taken reports on the urine of 19 patients at Barnsley Hall and 4 in the Queen Elizabeth Hospital for review. At Barnsley Hall *B. proteus* was reported present 34 times, *Ps. pyocyanea* 58 times, *Bact. coli* 137 times, non-hæmolytic streptococci 71 times, and other organisms twice. At the Queen Elizabeth Hospital *Bact. coli* was reported 19 times, *Ps. pyocyanea* 9 times, *B. proteus* 5 times, enterococci 4 times, staphylococci 4 times, non-hæmolytic streptococci 6 times, and various other organisms, such as monilia and diphtheroids, occasionally. Again it was usual for three or four organisms to be present together; and when the four common organisms were entrenched in the bladder they seemed rarely to disappear; occasionally one or other would not be reported for a few tests, but would reappear later.

It is noteworthy that some organisms do not flourish, and that the flora remains so constant and restricted.

Some ureters were catheterised, and there are records of 7 cases: *Bact. coli* was present alone in 5, in 6 it was present with other organisms; and the 7th was sterile. This finding supports the known invasive property of this organism in the urinary tract. *Strep. fæcalis* is probably not highly pathogenic, and perhaps the same can be said of *Ps. pyocyanea.*

We began with the administration of a sulphonamide in small doses (0 5 g. t.d.s.), and were disappointed to find pyrexial attacks extremely frequent. As emerged later, the organisms, including the varieties of *Bact. coli*, were insensitive to sulphonamides when tested in the laboratory. Since we suspected that the small doses used routinely would allow an insensitive strain to survive, we made a practice of changing to another sulphonamide if a pyrexial attack developed; but even so, the results were disappointing. Mandelic acid also proved unsatisfactory; it did not seem to control pyrexial attacks, and it tended to upset the stomach. The soil matters more than the seed, and, in the treatment of the spinal patient, fresh air, blood-transfusions, and tasty food are of supreme importance.

Finally, we formed the following opinions:

(1) Penicillin was by far the most successful substance for ending a pyrexial attack.

(2) Ammonium chloride, grains 15 four times a day in capsules, was the best routine urinary antiseptic, the pH of the urine being repeatedly checked and kept in the region of 5.

(3) For unexplained pyrexia lasting more than three or four days it was well to carry out pyelography, or else cystoscopy, with an injection of indigo-carmine, so that an obstructed upper urinary tract could be excluded. Where excretion of indigo-carmine was delayed, or there was evidence of dilatation of the ureter in the intravenous pyelogram, we inserted an indwelling catheter into the affected ureter, unless a stone shadow was revealed, in which case we undertook ureterolithotomy.

PYREXIAL ATTACKS

Bouts of pyrexia were common, especially in the months. The first problem was diagnosis, for were almost constant, and sometimes there were o wounds or incidental diseases, such as dipht infective jaundice, or pulmonary tuberculosis. Often the absence of clear evidence it was necessary to pres the presence of pyelonephritis.

The urine from the bladder was always infected sometimes almost clear to the naked eye. The ki were rarely, if ever, tender unless obstructed or the of gross cortical or perinephric abscess. Indeed, s surgical intervention was not indicated except for t complications, we came to regard the absence of s taneous pain and of tenderness as a strong reason persisting in medical treatment. This last conclu was not reached at first, because a patient injured a the level of the D10 might be expected to have an i sitive kidney and perhaps an insensitive kidney It is usually held that the sensory innervation of kidney is from D10–D12. One patient (sensory level complained of deep-seated pain below the right c margin, and on investigation nothing abnormal found except dilatation of the right kidney pelvis ureter. In this kidney stone was detected some mo later. In another patient (sensory level D10) the kidney became tender when a perinephric abscess formed.

In spite of these two clinical observations we did [illegible] rely solely on the abovementioned rule but also so to exclude an obstructed infected kidney by either excretory urography or cystoscopy with injection of indigo-carmine. We did not often find that a presumed pyelonephritis led to delay in the excretion of indigo-carmine; nor did we find, as some writers have maintained, that in such cases the ureter was always dilated. We usually made one or other of these investigations if pyrexial attacks did not respond to medical treatment.

CLOSURE OF THE BLADDER

Writers on the care of the bladder in the paralysed patient, at any rate immediately before the 1914–18 war, did not sufficiently emphasise how easy and desirable it is to close the bladder in the paraplegic patient. The sensation he has when the bladder is full may not be the normal sense of bladder distension—it may be only a tight feeling in the lower abdomen—but it may be sufficient to warn him that micturition is imminent. It evidently ascends in the sympathetic cord, and these afferent impressions are said to enter the cord as high as D6. One patient, injured in the region of D3, whose cord is grossly damaged, nevertheless has sufficient warning of impending micturition to be able to catch his urine in a vessel and to keep dry. Thus a patient with an intact micturition centre in the cord can often develop satisfactory automatic micturition with sufficient warning to enable him, in suitable circumstances, to dispense with an incontinence apparatus. ILATERAL CONGENITAL DISLOCATION OF RADIAL HEAD

R. K. MAGEE
M.D. Toronto, F.R.C.S., F.R.C.S.C.
MAJOR R.C.A.M.C.

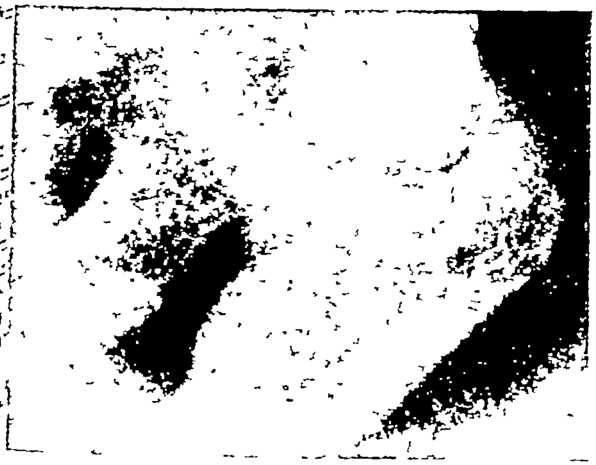
BECAUSE of its rarity and possible medicolegal signifi- ice the following case seems worth recording.

A man, aged 27, was admitted to hospital twenty-four urs after sustaining an injury to his left elbow by being own from a motor-cycle.

On examination there was swelling of the left elbow, with derness over the outer condyle. Flexion was limited to , and extension was 15° less than normal. Pronation l supination were painful and limited to half the normal ge.

Radiography revealed a dislocation of the head of the lius, without any fracture of the ulna or other bone (see ure). The head of the radius could be felt prominently der the swelling, and on supination and pronation it med not only to rotate on its long axis but also to move rough a small arc round the ulna, and it could not be luced. There was no shortening or other abnormality of e ulna.

Close questioning revealed that the patient had always d some limitation in flexion of both elbows, being unable to bring the finger-tips closer than 3 in. away from the shoulders. He had had slight pain in the elbows that had been diagnosed as arthritis. Radiography of the right elbow showed a condition similar to that of the left elbow—namely, a deformity of the head of the radius, which is rounded and has lost its cup-shaped articular surface. The head is bent forward and displaced forward, and the normal radial articular facet of the ulna is absent.



ateral radiogram of left elbow, showing congenital dislocation of head of radius.

The radiogram shows this case to be one of bilateral congenital dislocation, which is rare. In some reported cases it had been of medicolegal importance to establish that the dislocation was congenital and not traumatic.

Watson Jones[1] states: "Traumatic dislocation of the head of the radius unaccompanied by other injuries is practically unknown. It is almost invariably associated with a fracture of the upper shaft of the ulna."

This patient will recover his former range of movement and will require no specific surgery, unless arthritis justifies excision of the head.

I am grateful to Major R. M. Hall, R.C.A.M.C., for the radiogram.

TOXIC EFFECTS OF THIOUREA, THIOURACIL, METHYL THIOURACIL, AND AMINOTHIAZOLE IN THYROTOXICOSIS

MARGARET E. MORGANS
M.B. Lond., M.R.C.P.
ASSISTANT, MEDICAL UNIT, UNIVERSITY COLLEGE HOSPITAL, LONDON

SINCE Astwood (1943) first described the treatment of thyrotoxicosis with thiourea, abundant evidence has accumulated to show that the disease can be controlled by this and allied drugs (Cookson 1945, Himsworth 1943, 1944, Joll 1944, Nussey 1944, 1946). If these drugs had no toxic effects, their administration would probably be generally accepted as the treatment of choice. However, no preparation has yet been found which controls thyrotoxicosis and is entirely devoid of toxicity. It therefore seems desirable to assess the relative toxicity of the various preparations now available.

Agranulocytosis is the most serious and for practical purposes the only fatal toxic effect of the thiourea group of drugs. In the U.S.A., Moore (1946) found agranulocytosis in 19 (1·8%) out of 1091 cases, and Van Winkle et al. (1946) in 142 (2·5%) out of 5745 cases. The fatality-rates from agranulocytosis in the two series were 0·5% and 0·4%. All clinicians agree that a *leucopenia* may develop and that these drugs depress the level of granular cells of the blood. However, Perrault and Bovet (1946) and Bastenie and Tagnon (1946) claim that a related compound, aminothiazole, does not depress the level of these cells.

Other complications described include drug fever, rashes, petechiæ, glandular and splenic enlargement, joint effusions, and conjunctivitis (Cookson 1945, Eaton 1945, Himsworth 1943, 1944, Joll 1944, Newcomb and Deane 1944, Nussey 1944, St. Johnson 1944).

Pericarditis and heart-block were reported by Bain (1945); jaundice by Sloan and Sloan (1944), Kahn and Stock (1944), Paschkis (1944), and Gargill and Lesses (1945); and lesions resembling periarteritis nodosa by Gibson and Quinlan (1945).

Nausea, vomiting, and halitosis were observed by most writers in the early stages of treatment with thiourea. Swollen submaxillary glands were reported by Gargill and Lesses (1945) and by Williams and Clute (1944), and enlargement of the thyroid gland by Himsworth (1943) and Donald and Dunlop (1945).

In the investigation reported here the preparations tested and the number of cases in which each was used were as follows:

Preparation	*Chemical Composition*	*No. of cases treated*
Thiourea		7
Thiouracil		49
Methyl thiouracil		23
Aminothiazole		13

During the first three weeks, thiourea was given in the dosage of 3 g. daily as three doses of 1 g. Th first

TABLE I—EFFECT OF FOUR THIOUREA DRUGS ON GRANULAR CELLS DURING THE FIRST THREE WEEKS OF TREATMENT

Drug	Thiourea	Thiouracil		Methyl thiouracil	Amino-thiazole
		1·0 g. daily	0·6 g. daily		
No. of cases	7	29	20	23	13
Average initial level of granular cells per c.mm.	4700	4400	4400	4400	3300
Average change of level of granular cells per c.mm. from initial levels :					
End of first week..	..	−370	−970	−1000	+230
End of second week	..	−250	−850	+180	+300
End of third week	−560	−40	−340	+50	+100
Proportion of cases showing depression of absolute granular-cell count of 1000 per c.mm. from initial levels ..	14 %	31 %	30 %	39 %	38 %

29 patients treated with thiouracil were given 1 g. daily in five divided doses. The remaining 26 patients on thiouracil, those on methyl thiouracil, and those on aminothiazole received 0·6 g. daily in three divided doses. In these doses all the drugs appeared equally effective in the control of the thyrotoxicosis. Maintenance dosage varied according to the requirements of the patient, and with thiouracil, methyl thiouracil, and aminothiazole was usually 50–100 mg. daily. With thiourea the usual maintenance dose was 1 g. daily or twice daily.

INCIDENCE OF TOXIC EFFECTS

The assessment of the relative toxicity of the four drugs was made in the first eight weeks of treatment, because after that time toxic manifestations are so rare that insufficient were available for comparison.

Agranulocytosis may be arbitrarily defined as a fall in the granular-cell count to below 500 per c.mm., with or without infection. No case was seen while under treatment with any of these drugs during the first three weeks of heavy dosage, but 2 fatal cases were seen later.

Case 1.—A woman had received 65·2 g. of thiouracil in fifty-three days. This abnormally large dosage was used because the patient had had previous iodine treatment and appeared resistant to thiouracil.

Agranulocytosis developed on the fifty-third day after starting treatment with thiouracil and when the patient had been taking 0·6 g. daily for the previous sixteen days. No other drugs had been taken.

About fourteen days before thiouracil was stopped the patient had a furuncle in his nose, and a week later developed a whitlow. Terminally he had bronchopneumonia and a lung abscess.

The total white-cell count was 1500 per c.mm., with no granular cells. Marrow puncture showed that the agranulocytosis was of the non-maturation type. A blood-count before the patient left hospital showed no greater depression of granular cells than appears usual during treatment with the thiouracil group of drugs.

Case 2.—A woman reported to her private doctor with pneumonia and agranulocytosis, having taken 23·8 g. of thiouracil in thirty-six days (initial treatment was 1 g. daily for three weeks, and subsequently 0·2 g. daily). No details of marrow findings were available, but no granular cells were seen in a blood smear.

Both these cases of agranulocytosis occurred while the larger doses of thiouracil were being used, but with subsequent dosage no case has been encountered. This gives an incidence of 2·1% for the whole series, which agrees with the findings of Van Winkle et al. (1946). Both of our patients, however, died, so the fatality-rate was also 2·1%, whereas the fatality-rate for agranulocytosis in the corresponding American se was only 0·4%.

Leucopenia (granular cells less than 1500 per c.mm.) was seen in only 4 cases during the first eight w Of these, 3 were treated with thiouracil, 2 with 1 g. daily, and the other with 0·6 g. daily, and the fourth with methyl thiouracil. Severe leucopenia was not seen under treatment with thiourea or aminothiazole. A depression of the level of granular cells by 1000 or more per c.mm. was seen in many cases with all these drugs during the first three weeks. This period may be taken for comparison of this effect, since dosage in the four groups was comparable during this time. Excluding the thiourea group, where the number of cases is very small, the remaining three drugs depressed the granular cells with equal frequency.

Table I shows the effect of the different drugs on the average granular-cell count during the first three wee of treatment. The greatest fall appeared at the end of the first week, with a gradual improvement towards the end of three weeks. This fall was greatest in the methyl thiouracil series. Perrault and Bovet (1 and Bastenie and Tagnon (1946) claim that aminothiazole has no depressant effect on the granular cells. If the average figure in our 13 cases is considered alone there was no fall; but in two of them the granular-cell count was halved during the first three weeks, and in 38% of them the absolute granular-cell count was lowered more than 1000 per c.mm. from initial levels. In view of these findings and the relatively small number of cases in the series of Perrault and Bovet (1946) and Bastenie and Tagnon (1946) we feel that aminothiazole cannot be said to have no depressant effect on the granular cells. It has further serious drawbacks to its use which will be described below.

The incidence of other complications is shown in table II.

Drug fever, developing usually about the tenth day, was most common in cases treated with thiourea. The next highest incidence was among those treated with aminothiazole, and the lowest in those treated with thiouracil and methyl thiouracil.

Rashes, which included urticarial, erythematous, and maculopapular types, were seen most often with aminothiazole and were usually accompanied by fever. They were less common with thiourea, and none was seen wi thiouracil or methyl thiouracil.

TABLE II—TOXIC EFFECTS OF FOUR THIOUREA DRUGS DURING FIRST TWO MONTHS OF TREATMENT

Drug	Total cases treated	Agranulocytosis	Leucopenia*	Fever	Rash	Petechiæ	Enlarged glands	Enlarged spleen	Joint effusions	Pericarditis	Thyroid gland enlargement	Nausea	Halitosis	Salt taste	Myalgia	Jaundice
Thiourea 3·0 g. daily .	7	0	0	6	1	0	0	0	0	0	1	7	6	0	0	0
Thiouracil 1·0 g. daily .	29	2	2	2	0	1	0	0	0	0	0	0	0	0	0	0
0·6 g. daily ..	20	0	1	0	0	0	0	0	0	0	0	0	0	0	0	0
Methyl thiouracil 0·6 g. daily ..	23	0	1	2	0	0	3	0	1	1	2	0	0	0	0	0
Aminothiazole 0·6 g. daily ..	13	0	0	6	5	0	1	0	0	0	0	3	3	1	3	2

* Leucopenia—granular cells below 1500 per c.mm.

Petechiæ, without thrombocytopenia, were seen only duri treatment with thiouracil and not with any other drug.

Enlarged lymph-glands were most common with amin thiazole, less common with methyl thiouracil, and never se with thiourea or thiouracil.

Splenic enlargement was not observed.

Joint effusions and *pericarditis* were noted in 1 case treated with methyl thiouracil about the forty-second day of treatment, when the dose was still 0·6 g. daily.

Heart-block was not observed.

Toxic jaundice was seen only with aminothiazole. It developed in 2 patients, 1 of whom was gravely ill.

Conjunctivitis was seen with thiourea only.

Nausea and vomiting occurred in all cases treated with thiourea and in some treated with aminothiazole, but not with either of the other two drugs.

Halitosis was noted most often in patients receiving thiourea and occasionally in those receiving aminothiazole. It was not noted with thiouracil or methyl thiouracil. One patient taking aminothiazole noticed a salt taste in the mouth.

Enlargement of the thyroid gland was seen in one patient treated with thiourea, and in one treated with methyl thiouracil. Both of them showed signs of overdosage.

COMMENTS

Thiourea is to be avoided in the treatment of thyrotoxicosis in view of the high incidence of unpleasant side-effects and because it definitely depresses the level of granular cells in the blood. Though Continental workers have claimed that aminothiazole does not produce granulopenia, our results show that it may depress the granular cells. Because 2 cases of jaundice were seen among 13 patients treated, 1 being extremely ill, the use of aminothiazole was given up in this clinic. Methyl thiouracil and thiouracil both produce some depression of the white cells and in some cases leucopenia, but the incidence of other toxic effects is very low. Of the preparations now available they appear to be the drugs of choice in the treatment of the disease. Table II shows that there is no difference in the incidence of the toxic effects of these two drugs.

During the preparation of this paper supplies of propyl thiouracil have been received. Astwood and van der Laan (1945) found no toxic effects in a series of 37 cases treated with this drug. Our own experience is as yet insufficient to compare its toxicity with the other four drugs.

SUMMARY

The toxic effects of thiourea, thiouracil, methyl thiouracil, and aminothiazole during the initial phases of treatment of thyrotoxicosis are compared.

Thiourea and aminothiazole have many toxic effects and both depress the granular cells of the blood. Their use in clinical practice is no longer justifiable.

Thiouracil and methyl thiouracil are more satisfactory. Both depress the granular cells of the blood and in a few cases to a serious degree. During their use the incidence of other complications is much lower than with the other two drugs. Provided the patients so treated are carefully watched, both drugs can be used with a reasonable degree of safety.

Preliminary Communication

USE OF A TOURNIQUET TO PROLONG THE EFFECT OF PENICILLIN

In the search for a device to slow down the rate of absorption of penicillin into the circulation we have studied a simple method, which gives results very similar to those obtained by the oil-beeswax preparations. This is achieved by injecting penicillin subcutaneously in an area (thighs or arms) where the venous and lymphatic circulation can be delayed by exerting a light pressure with a rubber tourniquet. This pressure must not be sufficient to induce any unpleasant sensations in the limb.

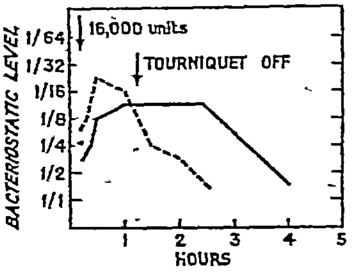

Fig. 1—Bacteriostatic levels of serum after injection of 16,000 units of penicillin with tourniquet applied (continuous line) and without tourniquet (dotted line). The curves represent the average of the results obtained with streptococci and with staphylococci as test organisms.

The penicillin concentration in the blood-serum was estimated by the capillary-tube method of Fleming, using streptococci, and by another method devised in St. Mary's Hospital with phenol red as indicator of growth of staphylococci. Both methods have given regular and reasonably comparable results.

The curves (figs. 1–4) show the amount of penicillin in the blood-serum (average of the results obtained with both methods) after subcutaneous administration. In each chart the broken line represents an experiment performed next day with the same dose in the same patient but without the tourniquet.

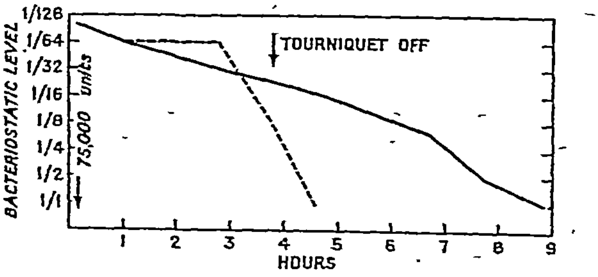

Fig. 2—As in fig. 1, but with 75,000 units of penicillin.

From these curves it appears that our method would be useful in reducing the number of injections needed to maintain a constant level in the blood without increasing the daily dosage of penicillin. Fig. 4 shows that the tourniquet should not be kept on too long, to avoid a double rise of penicillin concentration, which is probably

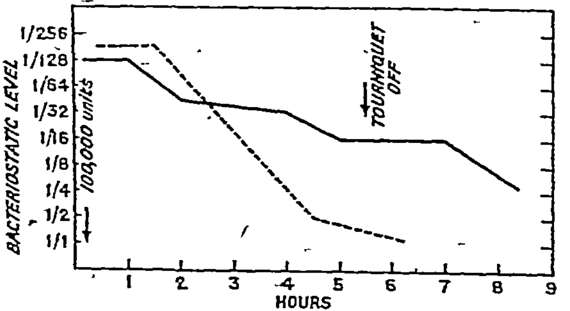

Fig. 3—As in fig. 1, but with 100,000 units of penicillin.

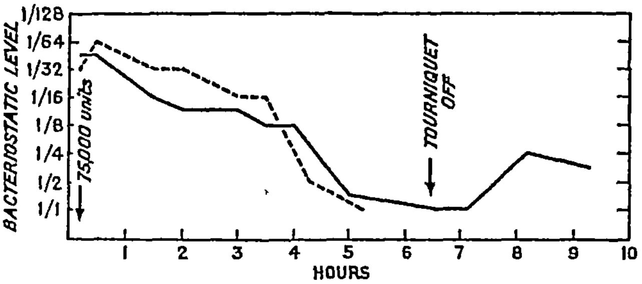

Fig. 4—As in fig. 2, but tourniquet was taken off late, causing a double rise of penicillin concentration.

less efficient than a constant level. In our experiments the time for which the tourniquet was applied varied from an hour for injections of 10,000 units to five hours for injections of 100,000 units; it must be progressively lengthened for higher doses.

With this method of administration the number of injections can be reduced to three of 75,000 units in 24 hours or five of 100,000 units in 48 hours without letting the penicillin concentration fall below the lowest effective level. An effective concentration of penicillin during 24 hours is also to be expected after a single injection of 600,000–800,000 units.

Reviews of Books

Modern Attitudes in Psychiatry

March of Medicine 1945, no. x of the New York Academy of Medicine lectures to the laity. By IAGO GALDSTON, M.D.; JAMES H. WALL, M.D.; G. CANBY ROBINSON, M.D.; FRANZ ALEXANDER, M.D.; Colonel WILLIAM C. MENNINGER; EDWARD WEISS, M.D. New York: Columbia University Press. London: Oxford University Press. Pp. 150. 13*s.* 6*d.*

THESE "lectures to the laity" of the New York Academy of Medicine are all worth reading. Colonel Menninger tells concisely how the American Army organised its psychiatric service during the war; and if Dr. Robinson and Dr. Weiss write for laymen rather more pointedly than the others, they still have much to say that will be unfamiliar to many medical readers. The outstanding essay, however, is Dr. Alexander's on present trends and future outlook, a rewarding study for those who like definition to precede discussion. He is concerned with the "history of scientific thought" in psychiatry, and traces the progress of its "etiological orientation." Scientific psychiatry began, he says, when mental changes were correlated with neuropathological conditions, and it was possible to adopt the hypothesis that some neuropathology would be found in all psychiatric conditions. This was first put forward somewhere in the eighteenth century and was in its heyday in the first decade of the twentieth. In the meantime, Freud had introduced his new and revolutionary idea that psychological disturbances had psychological antecedents. This paved the way for the stage which psychiatry is now reaching—the anthropological:

> "This cultural point of view sharpens our eyes for detecting in the kaleidoscopic variety of emotional disturbances the common features determined by the milieu to which every person growing up in the same society is exposed. . . . Psychiatry is concerned not only with therapy but also with prevention. Large scale prevention is essentially a problem of education which requires a keen understanding of prevailing culture patterns."

The whole essay is in a sense a tribute to Freud, but not to Freud as the repository of revealed truth. It is not even because of Freud's own contribution that Dr. Alexander puts him among the great, but because he was the first explorer in a new territory into which others can now follow and journey far beyond the reach of the pioneer.

Physiologie pathologique et traitement chirurgical des maladies artérielles de la vaso-motricité

RENÉ LERICHE, professor, Collège de France. Paris: Masson. Pp. 304. Fr. 280.

Thromboses artérielles

R. LERICHE; with the collaboration of IVAN BERTRAND, director of the institute of neurobiology at the Salpêtrière. Paris: Masson. Pp. 534. Fr. 600.

IN the field of vascular disorders few people have had wider experience than Leriche. His interests have been both surgical and pathological, and his experimental work is widely known. In his two latest books, clinical methods have been supplemented by oscillometry, whose limitations he recognises, and arteriography, examples of which illustrate the text. More precise measurements by, for instance, plethysmographic or skin-temperature methods have not been attempted.

The books report his lecture courses for 1943 and 1944, and the first volume includes sections on burns and frostbite, "shock," hypertension, arterial spasm, and the Raynaud phenomenon. There are general preliminary chapters on arterial and capillary pathology. On the surgical treatment of essential hypertension—a subject of much interest at the moment—he has little to contribute, contenting himself with recording the results obtained in America by White and Smithwick. In England, where Raynaud's phenomenon is regarded, according to the teaching of Lewis, as due to hypersensitivity of the digital vessels to cold, readers may be surprised to find stellate ganglion damage, demonstrated histologically in sections reproduced in the text, held responsible for the disease.

The second volume, of more interest to the surgical reader, deals with arterial thrombosis after trauma, with the Volkmann contracture, with arterial disease in thrombo-angiitis obliterans, diabetes, and old age, and with coronary thrombosis; case-histories illustrate the author's points, but surgical treatment is discussed without much detail. Leriche advocates unilateral adrenalectomy at an early stage of Buerger's disease—a measure based on histological abnormalities found in the suprarenals at autopsy, and on animal experiments by his colleagues. Both he and Oppel claim promising results in arresting the disease.

A long and informative section is given up to penicillin and streptomycin in the 1946 YEAR BOOK OF GENERAL THERAPEUTICS (Chicago: Year Book Publishers. London: H. K. Lewis, pp. 443, 21*s.*), edited by Dr. Oscar W. Bethea. Advances in sulphonamide therapy are also fully reviewed, and there are sections on thiouracil, the treatment of malaria and syphilis, vaccines, anæsthetics, and drugs acting on the circulatory and autonomic nervous systems.

Dr. Evarts A. Graham, in his introduction to the 1946 YEAR BOOK OF GENERAL SURGERY (Chicago: Year Book Publishers, London: H. K. Lewis, pp. 679, 21*s.*), draws attention to accounts of Crafoord's operation for coarctation of the aorta, and Blalock's operation for the relief of pulmonary stenosis in blue babies. Other subjects covered are the use of penicillin in the treatment of appendicitis and of brain abscess, operations for idiopathic dilatation of the œsophagus, and advances in anæsthesia.

The nutrition panel of the food group of the Society of Chemical Industry invited 32 scientists interested in food to read papers on different nutritional problems before its members. These papers were revised and brought up to date by their authors, edited by Mr. A. L. Bacharach and Mr. T. Rendle, and published, with an introduction by the late Sir Joseph Barcroft, F.R.S. (THE NATION'S FOOD, London: Society of Chemical Industry, pp. 349, 18*s.*). Here is everything a dietitian, a scientific caterer, and a physician needs to know about the chemistry and physiological values of the nation's food. There is, moreover, a considerable amount of "fine confused feeding" for the market-gardener, the stock-breeder, the cook, and the (earnest) politician. Altogether this is a book to be commended.

an antacid and starch digestant

Takazyma

TAKAZYMA is a pleasantly flavoured combination of insoluble alkaline carbonates with Taka-diastase and aromatics. It is unique in that it is the only antacid powder containing the potent starch-digesting enzyme, Taka-diastase, one part of which will liquefy three hundred parts of starch in ten minutes.

TAKAZYMA alleviates gastric irritation, neutralizes acidity, and assists starch digestion. It is ideal for the treatment of hyperacidity as it neutralizes excess of acid without the risk of producing alkalosis or stimulating late secretion of acid.

TAKAZYMA is especially beneficial in the management of peptic ulcer. In addition to its antacid action and soothing effect upon the gastric mucosa, it converts starch into soluble dextrose and ultimately into maltose, thus assisting in preventing flatulence and distension.

PACKAGES

TAKAZYMA is now available in the convenient form of TAKAZYMA LOZENGES in bottles of 30 and 100, in addition to the powder form which is available in jars of 2 ozs. and 1 lb.

'SOLUTHIAZOLE'

BRAND

neutral soluble sulphathiazole derivative

The soluble sodium salts of the heterocyclic derivatives of sulphanilamide such as sulphapyridine, sulphathiazole and sulphadiazine are strongly alkaline in reaction and their employment both parenterally and topically is subject to limitations.

'Soluthiazole' is the sulphathiazole analogue of 'Soluseptasine' and presents sulphathiazole in the form of a soluble compound which produces approximately neutral solutions in water.

It provides a means for the parenteral administration of sulphathiazole by either the intravenous or intramuscular route, and for its topical application.

The chief clinical indication of 'Soluthiazole' is to initiate therapy in patients who are acutely ill or to treat patients who are unable to take sulphathiazole by mouth. It may also be used by topical application in the treatment of infected conditions of the conjunctival sac, nasosinuses, joint cavities, pleural and peritoneal sacs.

SUPPLIES :—

'Soluthiazole' is supplied as a 45 *per cent.* sterile neutral solution (5 c.c. containing the equivalent of 1 gramme of Sulphathiazole) in ampoules of 5 c.c. (boxes of 6 and 25) and in multi-dose containers of 25 c.c.

THE LANCET

LONDON: SATURDAY, APRIL 19, 1947

Grouping of Hospitals

VERY soon the new regional hospital boards will be appointed and will have to face the problem of forming hospitals into groups under the care of hospital management committees. "The object in forming a group," said the London survey,[1] "is to provide a pool of accommodation and treatment facilities which can be used as a single whole. The specialist medical staff should be common to all the units in the District Hospital group, and nursing staff should also be common, particularly for the purpose of training. In planning the coördination of the service, the first step is to determine the units to be included in the group; the second is to determine which inpatient and outpatient services can most efficiently be provided at the various units and how special branches should be allocated between them." These are most desirable objects, and clearly a large measure of grouping must be undertaken if they are to be achieved. Nevertheless it is worth recalling that at the time when the surveys were made the conception of regional organisation had not been developed; and some of the purposes for which grouping was then recommended might now be more easily achieved through regional influence on such matters as distribution of consultant staff and location of specialist units. Moreover these surveys, invaluable though they are, took little account of two practical issues which have since become much more prominent—namely, the extreme shortage of nursing staff in many hospitals and the urgent demand for decisions on priorities for development. These are two aspects of one problem which cannot be dissociated from any decisions taken in regard to the grouping of hospitals.

The nursing problem is without exception the most critical with which the regional boards will have to contend, and it would be folly to proceed with grouping of hospitals before examining the effect this grouping is likely to have on the recruitment and retention of nursing staff. As we have already noted,[2] many local-authority hospitals are proving unable to attract and retain sufficient nursing staff to keep their beds open, and the number of beds in use is therefore tending to fall rather than rise. Inclusion of such deficit hospitals in a group which contains a teaching hospital should tend to ease their situation, since generally speaking the tradition and reputation of the voluntary teaching hospitals is such that they should be able to enlarge their schools and take over the staffing of all the hospitals in their group. But where the local-authority hospital, by virtue of its size, becomes the major unit of a group, and decides to unify the nursing staffs under its control, the result may be very different and perhaps disastrous; for there is no solid ground for supposing that girls who are at present willing to work in the small voluntary hospitals, because of the "homely atmosphere," will be forthcoming if control passes into the hands of the large ex-local-authority neighbour, whatever new flag it flies. When discussing projects for expansion of existing hospitals or for erection of new ones it is well to recognise that they are primarily contingent not on money, or on labour, or on the organisation of medical staff, but simply on securing nurses. Until the decline in the nursing staff of the local-authority hospital of today has been arrested and reversed, expansion is likely to be limited to those hospitals—often quite small—which can get nurses and can keep them. Approval of plans for extension must depend primarily on the ability of the hospital in question to find its complement.

The surveys provide material on which the regional boards can work; but the surveyors could not give each hospital an opportunity of stating its point of view at all fully, and more information will in fact be required before the new boards can be sure of grouping all their hospitals in the way best suited to their area. Estimates for expenditure, however, will need to be submitted next autumn in anticipation of the appointed day in April, 1948, when hospitals will become an Exchequer responsibility; and since the management committees will be responsible for preparing these estimates there seems at first sight to be no way of escaping early demarcation of the groups they are to manage. The only alternative which appears feasible is that some of the existing hospital committees might be given, temporarily, the functions of hospital management committees—without prejudice to any future arrangements in regard to grouping which the board may think desirable. This would have the merit of enabling the boards to proceed at their own pace, and get to know the personnel and facilities of the various hospitals under their care, which would put them in a better position to judge the probable repercussions of any proposed grouping and alteration in function. In some cases the advantages of an immediate merger are of course overwhelming, but in others there is grave risk of friction and misunderstanding: there are places where the best results might be obtained in the first instance by unification of the medical staff and cross-representation of lay personnel, and others where some considerable time must elapse before it is clear where a unit would best fit into the new scheme. The main—and serious—objection to postponement of grouping is the position of the local-authority hospitals, which cannot continue to be run by their present owners yet seldom have committees qualified to accept responsibility for their management. But would it be impossible, where it appears desirable for a local-authority hospital to remain for the time being outside a group, to appoint an interim committee to manage it?

The case for avoiding a rigid time-table is reinforced by the desirability of experiment. It has often been said that if a group is to provide a complete range of general and specialist services (including maternity, infectious diseases, and chronic sick) it may need

Radiophosphorus

PHYSICISTS like Sir JAMES CHADWICK[1] make it clear that artificially produced radioactive elements prepared in atomic piles will soon be readily obtainable for the treatment of disease. Two questions at once arise: for what conditions is such radioactive treatment useful, and how is the "dose" to be controlled?[2] It will be some time before facts and figures are gathered; but one of these elements—the isotope of phosphorus, known as radiophosphorus or P^{32}—has been on trial in the United States for 10 years, and Reinhard et al.,[2] who have reviewed the subject, show that a good deal of information has been gained about its uses and limitations.

The P^{32} used was prepared in the cyclotron, which produces much smaller quantities than the atomic pile. The isotope loses radioactivity by giving off beta rays of high energy that affect surrounding tissue, and in so doing is transformed to stable sulphur. Its half-life is 14·3 days—i.e., the radioactivity of a dose is down to half in 2 weeks, a quarter in 4 weeks, and so on. This is a convenient rate of decay, short enough to enable results to be controlled, yet long enough to ensure the protracted radiation of tissues which is important if, as has been suggested, cells are affected only during mitosis. Studies of the fate of P^{32} in the body showed that it is rapidly taken up by both red and white blood-cells within the first 24 hours; the red cells lose their P^{32} after 48 hours, but leucocytes retain their quota for a very long time, mainly in the nuclei. The tissues that take up most P^{32} are bone-marrow, lymph-nodes, liver, and spleen; leukæmic tissues take up much more than normal tissues. Many, but not all, forms of neoplastic tissue selectively absorb radiophosphorus. The degree of cellularity influences the uptake—for instance, in Hodgkin's disease the uptake of P^{32} decreases with increasing fibrosis of the lymph-nodes—because P^{32}, like normal P^{31}, is built into nucleoprotein; so the tissues multiplying fastest take up most P^{32}. Since the presence of much P^{31} reduces the uptake of P^{32}, in therapy the proportion of P^{31} should be kept as low as practicable. Unfortunately with P^{32}, as with other lethal substances, the difference between the concentrations in neoplastic and normal tissue is not wide enough to allow the former to be destroyed without affecting the latter; if enough P^{32} were given to destroy all the leukæmic cells, the tissues producing red cells and platelets would also be fatally affected.

Radioactive phosphorus was first used for treatment in 1936; and, since the results were published by LAWRENCE[3] in 1939, reports on the treatment of over 400 patients have appeared. REINHARD and his colleagues find that only 140 of the reports are sufficiently detailed for analysis, but by adding 155 cases of their own they have data from nearly 300 patients to draw on. The radiophosphorus was used in the form of dibasic sodium phosphate in an isotonic solution (15 mg. Na_2HPO_4 per c.cm.). The initial activity of such a solution was 0·20–0·40 millicuries per c.cm.; it gradually lost activity, but could be used until 0·04–0·05 millicuries per c.cm. was reached. Small frequent intravenous injections were given in preference to doses by mouth; the initial dose was 0·1–2·5 millicuries, and treatment was at first given two or three times a week. When the oral route was used the doses were larger, since only about 75% of the dose is absorbed. For comparison with X-ray treatment it has been calculated that if 1 millicurie of P^{32} is retained for 24 hours by a 70 kg. adult, the effect will be equivalent to 0·6 röntgens of whole-body radiation. The dose was carefully controlled by watching changes in the peripheral blood; in leukæmias with high white-cell counts, and in polycythæmia, the aim was to restore the blood-count to normal. In other diseases control was not so easy; in malignancy and Hodgkin's disease treatment was continued until blood changes suggested that bone-marrow activity was depressed; leukæmic patients without a raised white-cell count received doses similar to those found effective in the commoner type; in a few patients serial bone-marrow punctures were used. The dose required to bring about a given effect varies greatly from patient to patient, even in clinically similar stages of disease. The dose must therefore be carefully controlled and adjusted to the response in every case.

The best results have been in polycythæmia vera. A first course of 3·5–4·0 millicuries is given, and then no more for 3 months; if symptoms are severe blood is withdrawn by venesection, because 30–60 days elapse before the P^{32} dose effectively lowers the red-cell count. After 3 months, if the count is above 6 million per c.mm., a second course of 1–3 millicuries is given, and some patients need a third course 3 months later. By then a remission is invariably present and no treatment is given until a relapse occurs; remissions last for some time (the longest was 33 months); only 8 out of 21 patients needed more than one course of treatment. ERF[4] has confirmed these findings: he quotes the cases of polycythæmia treated in five different American clinics; 124 had satisfactory remissions, 11 were unsatisfactory, and 5 died; the longest remission after one treatment was 5 years. He notes that iron or large amounts of red meat or liver in the diet, can stop a remission. In chronic myeloid leukæmia treatment greatly relieved the symptoms, reduced the size of the spleen, and produced a remission in the anæmia. During treatment the proportions of myelocytes and myeloblasts in the blood fell, just as with X-ray treatment. Several patients have had remissions lasting a year or more. Difficulties arose in adjusting the dose; an initial dose of 1–2 millicuries was followed by four doses of 0·5–1·0 millicurie at 3 or 4 days' interval, and then 0·5–1·0 millicurie was given weekly until the leucocyte-count fell to 30,000 per c.mm. The blood-count must be carefully observed throughout, because it is impracticable to adjust the dose on a body-weight basis. P^{32} did not affect acute relapses or typical acute forms; nor, oddly enough, did it reduce enlarged lymph-glands which had resisted X-ray treatment. In lymphatic leukæmia P^{32} gave less satisfactory results: a similar treatment scheme somewhat improved signs and symptoms, but not so much as in myeloid leukæmia; no patient obtained a remission lasting as long as a year, one

something like 1000 beds. In practice, however, the size of the group has to depend largely on the hospitals and specialists available, and the kind of locality in which they are placed: in some areas 1000 beds might be provided by one or two hospitals; but in others six or seven might have to be grouped together, and the advantages of the 1000-bed unit might be outweighed by the disadvantages of remote control. It is perhaps significant that the latest and most thorough of the American surveys—that made in Michigan—concludes that 750 beds is the maximum size for a general hospital if the management is to remain flexible and human. Have we any firm reason for supposing that 1000 beds will constitute a better unit than 750?

The Unburied Body

SINCE the snow melted there have been appeals for volunteers to search for dead sheep on some of the uplands whence water flows into our city reservoirs. The authorities concerned seem to have avoided alarmist remarks about the prospect of serious contamination of water-supplies from this source, but the public is perhaps unduly disposed to regard the unburied body, whether of animal or man, as a menace to health. Whenever, for example, there are reports of deaths in the mass, with delayed disposal of corpses, the newspapers speak of the likelihood of consequent epidemics of infectious disease. It may be worth considering, therefore, how far this risk is real.

Nobody, of course, except on grounds of necessity in an emergency, would defend the practice of non-disposal of the dead; but the danger that it causes to health may easily be exaggerated. Neither the older literature nor the reports of recent incidents in Europe, India, and the Far East provide evidence that the open exposure of collections of bodies to advanced putrefaction has in itself been responsible for any outbreak of infectious disease; nor, so far as we know, has disease attacked people burying bodies thus exposed. Confusion has undoubtedly arisen sometimes from the fact that when conditions are so bad that people no longer dispose of the dead there is usually a simultaneous failure of social organisation generally. Whether the massive death-roll has been due to famine, or epidemic disease, or both, the arrangements for feeding the population, preventing disease, and treating the sick have broken down in face of a crisis. With lowering of hygiene and loss of morale, conditions have deteriorated to a point where the dead lie unburied—the last state being a result of the first. The starving or sick wander, vainly seeking aid; they crawl from place to place until forced by weakness to remain in one spot, where they die. With gradual loss of self-respect their discharges are scattered without consideration; so if, as often, they are suffering from an intestinal infection, they can foul ground, pollute waters, and infect everything they touch with rich cultures of pathogenic bacteria. In this condition they remain indifferent to the thousands of flies which help to disseminate infection. Nevertheless, though such a state of affairs is evidently dangerous, it does not follow that the dead are themselves a source of danger.

When death overtakes the body, coliform and other intestinal organisms begin to invade the tissues, where they rapidly overgrow and crowd out the more de
gram-negative pathogenic bacteria. Immedi
after death from typhoid the spleen and mesen
glands may yield pure cultures of *Bacterium typho*
but a few hours later this organism can be reco
only by highly selective technique, and later none
the putrefactive bacteria will be found. Much
same sort of result is obtained with the inte
contents in salmonella or dysentery infections. Mo
of the experimental work on the viability of inte
pathogens has been concerned with voided disch
where the organisms are present in relatively
concentration, and it has been proved that in a
dry atmosphere and in sunlight the life of the
negative pathogenic bacteria is short. *Shigella*
may live for several days in fæces in the laborat
but exposed to the drying air and hot sun of
tropics its viability is much reduced. Similarly
vibrios of cholera may remain alive for many days
they reach water, but the thin stools from a ch
patient are rendered non-infective within an hou
so if allowed to dry quickly in sunlight. Subj
to anaerobic conditions within the dead body
vibrios of cholera die out very quickly, leaving
field to putrefactive organisms from the inte
The speed with which the latter invade the tissues
varies to some extent according to the disease respon-
sible for the death but mainly according to the
surrounding temperature. Tropical conditions lead
to very rapid multiplication of the putrefactive
bacteria, and very shortly after death the original
infective processes are completely masked by con-
taminating organisms. In temperate or cold climates
the march of events is retarded, and the resistanc
the gram-negative intestinal pathogens to cold ma
it easier to recover them post mortem. ZLATOGORO
in 1904 was able to cultivate *Pasteurella pestis* fr
the buboes of cadavers frozen for over 100 da
whereas with temperatures of about 100° F in Eg
the post-mortem diagnosis of plague in sporadic ca
was only possible when the material was obtai
very soon after death. Plague, typhus, and chol
are all diseases liable to cause mass death, in wh
the handling of the newly dead requires special p
cautions. Particular care is also needed in handli
anthrax. In cattle this disease always termina
as a septicæmia and frequently in an abrupt a
acute form so that groups of animals may be fou
dead or dying on the ground, which may be furtl
fouled by infective discharges escaping from the orifi
after death. Owing to the formation of spores in th
discharges the soil may remain infective for ma
years, and of all diseases anthrax is the one where
is most necessary that the body should be dispos
of without delay and by methods other than sim
burial.

It is clear, therefore, that there is some dang
from spread of infection from collections of expos
dead. But this danger (apart from animals dying
anthrax) appears to be no greater, and usually mu
less, than that attached to the same group during th
life. In the tropics failure to dispose of the de
adequately may result in more revolting and nause
ting conditions than are seen in cold climates, but tl
risk to public health is actually smaller there.

Radiophosphorus

Physicists like Sir James Chadwick[1] make it clear that artificially produced radioactive elements prepared in atomic piles will soon be readily obtainable for the treatment of disease. Two questions at once arise: for what conditions is such radioactive treatment useful, and how is the " dose " to be controlled?[2] It will be some time before facts and figures are gathered; but one of these elements—the isotope of phosphorus, known as radiophosphorus or P^{32}—has been on trial in the United States for 10 years, and Reinhard et al.,[2] who have reviewed the subject, show that a good deal of information has been gained about its uses and limitations.

The P^{32} used was prepared in the cyclotron, which produces much smaller quantities than the atomic pile. The isotope loses radioactivity by giving off beta rays of high energy that affect surrounding tissue, and in so doing is transformed to stable sulphur. Its half-life is 14·3 days—i.e., the radioactivity of a dose is down to half in 2 weeks, a quarter in 4 weeks, and so on. This is a convenient rate of decay, short enough to enable results to be controlled, yet long enough to ensure the protracted radiation of tissues which is important if, as has been suggested, cells are affected only during mitosis Studies of the fate of P^{32} in the body showed that it is rapidly taken up by both red and white blood-cells within the first 24 hours, the red cells lose their P^{32} after 48 hours, but leucocytes retain their quota for a very long time, mainly in the nuclei. The tissues that take up most P^{32} are bone-marrow, lymph-nodes, liver, and spleen; leukæmic tissues take up much more than normal tissues. Many, but not all, forms of neoplastic tissue selectively absorb radiophosphorus. The degree of cellularity influences the uptake—for instance, in Hodgkin's disease the uptake of P^{32} decreases with increasing fibrosis of the lymph-nodes—because P^{32}, like normal P^{31}, is built into nucleoprotein; so the tissues multiplying fastest take up most P^{32}. Since the presence of much P^{31} reduces the uptake of P^{32}, in therapy the proportion of P^{31} should be kept as low as practicable. Unfortunately with P^{32}, as with other lethal substances, the difference between the concentrations in neoplastic and normal tissue is not wide enough to allow the former to be destroyed without affecting the latter; if enough P^{32} were given to destroy all the leukæmic cells, the tissues producing red cells and platelets would also be fatally affected

Radioactive phosphorus was first used for treatment in 1936; and, since the results were published by Lawrence[3] in 1939, reports on the treatment of over 400 patients have appeared. Reinhard and his colleagues find that only 140 of the reports are sufficiently detailed for analysis, but by adding 155 cases of their own they have data from nearly 300 patients to draw on. The radiophosphorus was used in the form of dibasic sodium phosphate in an isotonic solution (15 mg. Na_2HPO_4 per c cm.). The initial activity of such a solution was 0·20–0·40 millicuries per c cm ; it gradually lost activity, but could be used until 0·04–0·05 millicuries per c.cm. was reached. Small frequent intravenous injections were given in preference to doses by mouth; the initial dose was 0·1–2·5 millicuries, and treatment was at first given two or three times a week. When the oral route was used the doses were larger, since only about 75% of the dose is absorbed. For comparison with X-ray treatment it has been calculated that if 1 millicurie of P^{32} is retained for 24 hours by a 70 kg. adult, the effect will be equivalent to 0·6 röntgens of whole-body radiation. The dose was carefully controlled by watching changes in the peripheral blood; in leukæmias with high white-cell counts, and in polycythæmia, the aim was to restore the blood-count to normal. In other diseases control was not so easy; in malignancy and Hodgkin's disease treatment was continued until blood changes suggested that bone-marrow activity was depressed; leukæmic patients without a raised white-cell count received doses similar to those found effective in the commoner type; in a few patients serial bone-marrow punctures were used. The dose required to bring about a given effect varies greatly from patient to patient, even in clinically similar stages of disease. The dose must therefore be carefully controlled and adjusted to the response in every case.

The best results have been in polycythæmia vera. A first course of 3·5–4·0 millicuries is given, and then no more for 3 months; if symptoms are severe blood is withdrawn by venesection, because 30–60 days elapse before the P^{32} dose effectively lowers the red-cell count. After 3 months, if the count is above 6 million per c.mm., a second course of 1–3 millicuries is given, and some patients need a third course 3 months later. By then a remission is invariably present and no treatment is given until a relapse occurs; remissions last for some time (the longest was 33 months); only 8 out of 21 patients needed more than one course of treatment. Erf[4] has confirmed these findings: he quotes the cases of polycythæmia treated in five different American clinics; 124 had satisfactory remissions, 11 were unsatisfactory, and 5 died: the longest remission after one treatment was 5 years He notes that iron, or large amounts of red meat or liver in the diet, can stop a remission. In chronic myeloid leukæmia treatment greatly relieved the symptoms, reduced the size of the spleen, and produced a remission in the anæmia During treatment the proportions of myelocytes and myeloblasts in the blood fell, just as with X-ray treatment. Several patients have had remissions lasting a year or more. Difficulties arose in adjusting the dose; an initial dose of 1–2 millicuries was followed by four doses of 0·5–1·0 millicurie at 3 or 4 days' interval, and then 0·5–1·0 millicurie was given weekly until the leucocyte-count fell to 30,000 per c.mm The blood-count must be carefully observed throughout, because it is impracticable to adjust the dose on a body-weight basis. P^{32} did not affect acute relapses or typical acute forms; nor, oddly enough, did it reduce enlarged lymph-glands which had resisted X-ray treatment In lymphatic leukæmia P^{32} gave less satisfactory results: a similar treatment scheme somewhat improved signs and symptoms, but not so much as in myeloid leukæmia; no patient obtained a remission lasting as long as a year, one case completely failed to respond, and some had to have blood-transfusions for the anæmia. *Monocytic* leukæmia did not respond at all, and patients with multiple myelomas obtained only insignificant relief. In Hodgkin's disease and lymphosarcoma the results were poor compared with those of radiation. A few patients with other forms of malignancy, such as carcinoma of the breast and gall-bladder, and malignant melanoma, were given P^{32} without any effect.

A technical difficulty in radiophosphorus therapy is the estimation of activity in terms of millicuries. At present different laboratories obtain widely different figures—for instance, the activity of a sample of P^{32} was estimated as 100 microcuries at one laboratory and 240 microcuries at another. As KRAMER points out in an appendix to REINHARD's article, this difficulty has led to discrepancies in the recommended dosages of P^{32}. A definite standard of measurement is vitally important with so acti substance.

Radiophosphorus, then, can be said to have p superior to other measures only in polycyth vera and chronic myeloid leukæmia; in these co tions the results seem to last longer than with X- therapy, there is no radiation sickness, and the t ment is more comfortable for the patient. There no evidence that P^{32} prolongs life any more t X-ray treatment does. The disadvantages of phosphorus are its scarcity, which one hopes temporary, and the fact that it must be used after manufacture, the lack of an agreed stand for measuring its activity, and the need for c individual control during treatment. Such active materials are clearly going to be useful, this is another set of therapeutic agents that be safely used only in specially equipped clinics are outside the province of the general practitioner

Annotations

THE GENERAL PRACTITIONER'S PENSION

LAST week Dr. Gordon Ward wrote us a letter condemning the proposal to pay pensions to general practitioners according to the number of years they have spent in the National Health Service and their average income during all those years. He compared their treatment unfavourably with that of the lay administrator, whose entry to the Civil Service at an earlier age gives him more years of service, and whose pension is based on his income during his last three years, when his salary is at its highest. Readers may well have wondered how such a proposal came to be made. The truth is that while there is no difficulty, and ample precedent, in arranging superannuation for anyone paid on an agreed salary scale, it has hitherto been deemed impracticable to devise a satisfactory scheme for people whose income fluctuates from year to year in response to factors not easily assessed actuarily. Once, therefore, the Government conceded that the remuneration of the general practitioner in the new service should be not solely, or even mainly, by salary, but should chiefly accrue from a continually changing number of capitation units, it was not surprising that difficulties and anomalies arose. In fact it was more surprising that the Government still felt able to attempt any superannuation scheme at all for general practitioners.

Dr. Ward's point about length of service has long been a grievance of medical officers in local-government work, who feel that they are penalised vis-à-vis their non-medical colleagues whose superannuation has perhaps accrued from the day they left school and came to learn their profession in the council's employ. Though the fact that the doctor reaches his office some ten years later, after a long and expensive undergraduate and postgraduate training, may be partly offset by relatively higher remuneration in the junior years of employment, the anomaly remains a cause of irritation. This could best be overcome if it were possible to establish that the unavoidable time-lag was compensated by allowing bonus years, counting for superannuation, to be added at intervals to those actually served by the doctor.

As for the period over which the average remuneration should be assessed for pension purposes, Dr. Ward agrees that the usual Civil Service practice of taking the final three years would be unfair, because for the general practitioner these are often years of waning earnings. Unfortunately his alternative suggestion, that the average of the three best consecutive years should be taken, could scarcely be accepted officially: to the Government actuary it must conjure up visions of doctors working for three hectic years to establish their claim to maxim superannuation, and thereafter steadily decreasing t load, secure in the knowledge that this will in no w affect their pensions. It seems inevitable that if pension is to vary with earnings it will have to be b on the average over a wide period. Hence, if we not accept the Government's proposal to take the ave age of the whole of the doctor's working years it mig be best to argue in favour of the average of those y when the doctor may be expected to be working optimum capacity—excluding his first years before b becomes established, and the last years before his retir ment when he would ordinarily be accepting fewer ne commitments.

Among his strictures Dr. Ward does not mention th disastrous effect these new provisions might have o any attempt to preserve present partnerships or promot group practice. Many doctors wishing to work togeth in the new service, and enjoy the advantages of grou practice, will want to find ways of sharing expenses an remuneration on a partnership basis—ways which wi not interfere with mutual aid, or with their encouraging and "feeding" a newcomer to the group. If, however, not only their present remuneration but their future pension prospects are to depend directly on the numbers patients on their individual lists, competition for patients is bound to be intensified, and the whole concept of group coöperation wrecked. We have always held that so far as general practice was concerned the test of success of the new service would be its ability to provide better conditions of practice—more coöperation between practitioners, opportunities for "graded specialism" with the wider use of diagnostic aids, and the sharing of ancillary help. Rather than have all these ends jeopardised by an ill-conceived pension plan, it might be better to leave the general practitioner outside the superannuation scheme altogether, adding enough to his remuneration to enable him to provide, by insurance or other forms of saving, for his own and his family's future.

REVIEW OF SILICOSIS

IN his Julius Wernher lecture to the Institution o Mining and Metallurgy on April 15, Major-General A. J. Orenstein, F.R.C.P., said that the important cause of silicosis is silica dioxide. With the exception of asbesto under certain conditions of handling in manufacture, the silicates produce a less deadly pneumoconioses; the suggestion that 'Sericite' (hydrated aluminium and potassium silicate) is the principal cause has not been substantiated. Silica damages the lung not as was once thought mechanically, but through slow solution. Animal experiments show that the smaller the particles the greater is the danger; this is at least partly due to the more rapid solubility of small particles, but another reason is that they remain longer in the air. Attention must be directed to minimising dust, especially fine dust; and there is some doubt as to the ability of water to remove the dangerous very fine particles from the air. On this point it is difficult to obtain convincing results: on the Witwatersrand gold mines it would take about thirty years to obtain suitable data, and there would be grave difficulty in the psychological reaction to a reversal of the accustomed wet-drilling routine. In practice, removal of dust by *suction at the drilling orifice* does not offer a satisfactory solution, at least in the Witwatersrand mines. At ore bins filtration has proved effective. Sprays deal partly with blasting dust, but its danger must be further neutralised by ventilation and by keeping miners away until the air is freed from dust and toxic fumes.

The place of aluminium in prevention is still undecided; the position has been fairly expressed in the joint report by the Council on Industrial Health and the Council on Pharmacy of the American Medical Association, which indicated that though in animal experiments aluminium has provided effective prophylaxis against the toxic action of relatively pure quartz, this does not necessarily hold for silicosis in man; the general use of aluminium, the report added, should be delayed until full trials have been completed, particularly in view of the known capacity of amorphous hydrated alumina to foster tuberculosis.

As regards *aluminium in the treatment of silicosis*, said General Orenstein, it is difficult to accept that any substance can reverse established fibrosis, though it may influence resolution of very early silicotic changes, before fibrosis is established. Subjective relief, or even improvement in breathing and general well-being, are poor criteria. "I would join Gardner and the American Medical Association in cautioning against reliance on any method of prevention which would push even ever so slightly into the background dust prevention and dust removal. Need I say then how much more blameworthy we should be if we allowed the mischief to happen and pinned our faith to a cure?"

PANEL LISTS

UNDER the pressure of war the regulations governing insurance practice were relaxed to allow principals to accept 500 patients beyond the ordinary maximum. Last January this concession was withdrawn; so the basic numbers now acceptable are, as before the war, 2500 for a principal (5000 for two partners, of whom one may have up to 3000) and 1500 for an assistant. Since 1938, however, the Minister of Health has approved, where necessary, percentage increases beyond this maximum, in view of the increment through the extension of the scheme to include juveniles who have reached school-leaving age. He has lately reaffirmed his willingness to receive applications both on this score and in the light of the increase, from 1942, of the income limit from £250 to £420, as well as for other special reasons. The increase normally granted for juveniles is 5%, and if a further 5% is conceded for the raised income-level doctors with the basic 2500 will again have nearly the 3000 patients permitted during the war.

It was hoped that the pre-war maxima, without increases, could be restored because the load arising from war-time extension of N.H.I. could now be transferred to doctors coming out of the Forces. This aim was abandoned for several reasons: (1) few panel doctors have *in fact anything* like the maximum permitted number of patients, and those with the largest lists usually work in highly industrial areas where most other doctors are reluctant to settle; (2) patients, it is said, attach themselves less to a doctor than to a particular surgery, and are unwilling to go to doctors newly arrived in an area; (3) the surplus patients would not provide a living for incoming practitioners; and (4) it is not worth disturbing the patients by insisting on their transfer at a time when the new service is only twelve months away. Not everyone will be convinced by this reasoning, which has won the day; strict adherence to the pre-war maximum would have provided employment in assistantships for at least some demobilised doctors until they found their place in the new service; and a few, having worked for a time in the industrial areas where the need is *greatest, might* have decided to stay there, thus making for a much-needed balance.

ARTIFICIAL INSEMINATION

THE Public Morality Council did a useful service last year in bringing together doctors, clergy, and lawyers to discuss *temperately* the difficult subject of *artificial* human insemination. The purpose of the conference (a report of which has now been published [1]) was not so much to reach conclusions as to uncover implications. Among the clergy there were speakers from the Church of England, the Roman Catholic Church, and the Free Churches; medical speakers included Dr. H. P. Newsholme, Mr. Kenneth Walker, F.R.C.S., Dr. William Brown, Dr. Mary Barton, Dr. Joan Malleson, and Mr. J. V. O'Sullivan, F.R.C.O.G.

In discussing the moral aspects of the practice, all the clergy were able to accept the principle of artificial insemination of the wife by the husband's semen, provided this was obtained from the vaginal pool after normal intercourse. The Church of England speaker was even willing to concede that, in his own *opinion*, where there was no other practicable alternative, the production of semen for the purpose by masturbation need not be condemned on moral grounds. All the clergy, however, found the principle of *artificial insemination with donor's* semen to be morally objectionable.

The legal drawbacks, some of which may not have been fully appreciated by doctors, were well set out by Mr. J. P. Ashworth. He made it clear that the signed statement of consent, usually obtained by the doctor from both the husband and wife before insemination with donor's semen (A.I.D.) is performed, is likely to be worthless legally. A better safeguard of the doctor would be some more formal type of consent, for example an oath; but few couples, he felt, would be willing to go *before* a commissioner of oaths on so personal a matter. Then, if the husband is registered as the father of the child, he and the mother are *making* a false statement under the Perjury Act, and could be prosecuted. Again, Mr. Ashworth had little doubt that the child is legally illegitimate, and questions of inheritance might turn on this. An assurance from the couple that no third *party* is interested cannot possibly be adequate, because legacies and bequests might be made later by relations ignorant that the child was illegitimate; and this *might* mean loss to other beneficiaries. Finally, there is the danger that, where several children in a neighbourhood are fathered by the same donor, some of them may later meet and marry; indeed, *the danger* of such incestuous matings cannot be wholly excluded, since the doctor must make a *point of* keeping the name of the donor secret.

Psychological difficulties between husband and wife, or arising in the child, were only superficially considered. Dr. Mary Barton drew *attention to the* resentment and frustration which a wife who knows herself capable of bearing a child may feel towards an infertile husband. Presumably this dissatisfaction could *not* be *wholly* relieved by a donor-pregnancy, but several of the medical speakers were confident that such a pregnancy usually has the effect of restoring harmony between the husband

---

[1] Artificial Human Insemination. London. Heinemann. Pp. 81. 3s. 6d.

and wife, and has in some cases prevented a marriage from breaking up. Of long-term effects on the children it is clearly too early to speak.

The doctors agreed that the cases in which donor insemination might be considered form only a very small proportion of all cases of subnormal fertility, which in many couples can be treated successfully in other ways. Dr. Margaret Hadley Jackson, who was not present at this conference, has found occasion to advise A.I.D. less than 40 times at an infertility clinic where more than 900 patients have been treated in eight years; about half of these 40 patients conceived as a result of the measure. Dr. Mary Barton is reported to have said that she and her colleagues had "had only about 300 children conceived by this means," over a period of five years—a number which seems large rather than small if Dr. Jackson's experience is a guide.

TREATMENT OF STARVATION

OUR knowledge of the effects and treatment of starvation has increased immeasurably during the last few years. The scanty data available in the early years of the late war have been shown to be largely inaccurate. The first fact which surprised many was the rarity of specific deficiency diseases in Europe when all food was scarce and a severe shortage of vitamins was to be expected. The cause of this appears to be twofold. First, starvation or semi-starvation lowers the metabolic processes and the requirement of vitamins and other essential nutrients. Secondly, in Europe, the shortage of food led to the introduction of breads of high extraction and an increased consumption of all types of vegetables, resulting in a proportionately higher intake of vitamins and mineral elements such as iron than are found in more refined normal diets. Some nutritionists had foreseen this and had realised that the problem of reinstatement would be mainly one of calories.[1] Conditions were different among prisoners in the Far East, where the inadequate food was also appallingly deficient in vitamins, so vitamin deficiency diseases were rife. In European concentration camps, on the other hand, what was encountered was simple gross starvation. There was comparatively little famine œdema, but severe diarrhœa was so common as to lead to the diagnosis of bacillary dysentery; mental apathy and physical lethargy were intense, yet people on the verge of starvation were often so finicky about their food as to refuse to eat what they disliked. In other respects—the extreme loss of fat and muscular tissue, the lowering of the hæmoglobin and plasma-protein levels, and the high incidence of tuberculosis—the effects had been expected.

The greatest change has been in our views on treatment. On theoretical grounds, it had been believed that a valuable measure in the early stages of the treatment of severe cases was the parenteral administration of protein hydrolysates.[2] There was some evidence from India to support this belief.[3] But it was soon found that only in a very few cases, where it was impossible to feed the patients by mouth, were these preparations useful.[4] In almost all patients excellent results in the initial stages of treatment were obtained by oral feeding, and skim milk was better for this purpose than the usually very unpalatable protein hydrolysates. Lipscomb[5] gave skim milk, sugar, salt, and compound vitamin tablets for 3 or 4 days. This diet, which provided about 800 calories daily, was followed by one of about 1750 calories and finally by one of 3000 calories daily. The results reported by Dr. Murray in this issue suggest t at least after the initial stages, a much higher calo intake than 3000 is advisable. When his patients w seen, 2 or 3 weeks after liberation, they were still so 23% below their normal weight and still apathetic and dull. Within a very short time on a diet of the enormous calorie value of nearly 8000 daily they improved greatly. They gained over 2 kg. in weight in one week and continued to gain rapidly, though at a decreasing rate, for the whole of the 23 days during which they were observed. The most surprising feature was the tolerance which the patients showed to this huge intake. Not only were there no apparent ill effects but the rate at which they gained weight suggests that the diet was very well utilised.

Would it have been possible to give diets of such magnitude earlier? It is said[5] that in the first stages of treatment large amounts of food are harmful and may actually cause death. Yet Leyton[6] observed that Russian prisoners often ate large meals in the earliest stages of recovery with no untoward effects. It seems likely that, at any rate after the first few days, large diets *such as those used* by *Murray* would have accelerated recovery. The most encouraging lesson of Murray's experience, however, is that once improvement begins it normally leads to an uneventful and complete recovery.

GOOD NEIGHBOURS

THE help which the British War Relief Society of the U.S.A. gave us from 1939 to 1945 was as varied as it was discerning, and the record of what these Friends in Need[7] did for us shows how American resource and kindliness matched our changing wants. Nothing was too big—fleets of tea cars, mobile canteens, grants and equipments for clubs, rest-homes, hostels for tired workers, nurseries for evacuees, and equipment for hospitals. But equally nothing was too small—seeds for allotments, sweets in the pocket of a child's frock, crutches for orthopædic patients who would otherwise have had to stay in bed, and innumerable toys. As a final and permanent gift the society has left us with the new surgical block at the Queen Victoria Hospital Plastic Surgery and Jaw Injury Centre at East Grinstead.

BETTER LIMBS

ARTIFICIAL limbs, even the best of them, will always fall short of the real thing; and perhaps the worst disaster for the limbless would be the development of stereotyped patterns on which it was thought no improvement could be made. So far is the Limb Fitting Centre of Queen Mary's Hospital, Roehampton, from this sterile and complacent state that a new research department has been established there; and on March 25 a meeting was arranged to demonstrate recent designs and appliances. Dr. John Craft discussed problems of suspension of artificial legs. For women, with disarticulation at the hip, or with above-knee or below-knee amputations, the limb can be suspended best, he finds, from a corset instead of from the old pelvic belt. The corset is made on ordinary lines, but laced up the back, and the limb is held by an elastic strap in front and another behind. Patients wearing such limbs were able to show that they are well retained, and that the stump does not tend to leave the socket when the wearer sits down. A shaped belt is now being used for men, instead of the pelvic band, and this, like the corset, has the advantage that the wearer can dispense with shoulder-slings. On a recent visit to Germany, Dr. Craft found the suction-socket almost universally used, and he is reviving this device here. The socket closely fits the stump, and a valve at the side allows air to leave but not to enter; the partial vacuum thus produced holds the limb firmly in place. This works well, enabling the wearer to do without suspension from the pelvis, as various patients demonstrated. Further experiments on these lines are planned. Light elbow crutches, which can be taken to pieces for packing, are another German device which have advantages over English patterns. The Ministry of Pensions standard tool-holder for attachment to artificial arms is well known, and can be used for digging, working with tools, and batting at cricket; but the research department are also studying new designs for mechanical hands and fingers. The problems of the bath-tub have always puzzled the man who has lost both arms, because artificial limbs are damaged by water. A simple covering for the stumps, made of rubber, has now been made and fitted with a device to which a shaving-brush and razor can be fixed.

German surgical measures include the Sauerbruch cineplastic amputation,[1] and the Krukenberg operation by which the forearm bones are made to act like a pair of pincers.[2] Prof. T. P. Kilner, discussing the results—which were demonstrated by a group of patients brought over from Germany—said that the amount of training necessary before either kind of stump could be used properly was so great that a man with a single arm amputation would seldom bother with it, preferring to use only his sound arm. For those who have lost both limbs, the Krukenberg procedure makes an appliance unnecessary and gives a good powerful grip; he thinks it useful and worthy of further consideration.

Sir Charles Darwin, F.R.S., chairman of the Ministry of Pensions standing advisory committee on artificial limbs, remarked that the versatility of the natural hand and arm are such that an infinite number of substitutes can be explored; and not only many mechanical problems of the artificial hand but problems in the training of other muscles in delicate control are still unsolved. The difficulties are such that the committee favour the development of new mechanical appliances rather than any attempt to reproduce finger movement faithfully. Several such appliances were demonstrated, including a nailbrush with two rubber suckers on the back; stuck on any flat surface, this can be used on the sound hand. Patients who joined in the discussion urged that these and other simple and helpful devices should quickly be made available to the limbless.

PREVENTIVE ASPECT OF REABLEMENT

So much has been written about fitting the disabled into useful employment that many people now regard reablement from the single standpoint of the resettlement in industry of those who are permanently crippled by injury or disease. In a lecture given recently at the Royal Empire Society, Mr. H. E. Griffiths said that on visiting Poland he found that interest centred almost entirely on the possibility of fitting amputees for suitable work; and the same attitude was noticeable at the International Red Cross Conference last October.

This limited view of reablement is unfortunate. In tuberculosis, for example, its rôle is partly to ensure appropriate occupation for the man or woman permanently handicapped by the disease, but far more to prevent or limit permanent disability by effective treatment and aftercare. The same is true of all potentially disabling disease and injury, and it is the preventive aspect of reablement with which doctors are chiefly concerned.

An illustrated booklet[3] just issued by the Ministry of Health gives an excellent account of what the Ministry has done to increase reablement facilities and what it hopes to do under the National Health Service. In 1939 hardly any hospitals in Great Britain were able to do all that was necessary in this line for their patients, but now no less than 204 offer comprehensive reabling treatment, including physiotherapy, gymnastic exercises, remedial games, and occupational therapy, while a further 129 already possess partial facilities and many others are making plans. The process of reablement, in both hospitals and special centres, is clearly described, and the booklet deserves wide circulation among doctors and all others whose aim is to restore health.

VELOCITY OF BLOOD-FLOW IN PREGNANCY

SOME have said that the velocity of blood-flow is decreased during pregnancy, while others believe it to be unaltered or increased. By observations every fortnight in 48 pregnant women, Manchester and Loube[1] seem to have settled the question. Estimating the arm-to-tongue time by the calcium-gluconate method, and the arm-to-lung time by the ether-paraldehyde method, they found that throughout pregnancy the velocity was within the normal limits—i.e., 9–16 sec. for the arm-to-tongue time, and 4–8 sec. for the arm-to-lung time. Nevertheless each trimester showed an increase in the mean velocity of blood-flow: thus in the first trimester 90% of the values for the arm-to-tongue time were between 10 and 14 sec., with the remainder between 14 and 16 sec.; in the second trimester only 4% were above 14 sec., with 19% less than 10 sec.; while in the third trimester 50% of the average values were under 10 sec. The practical implication is that in the latter part of pregnancy circulation-times at the upper limit of normality may suggest incipient heart-failure. The clinician cannot afford to neglect any method which may hasten the diagnosis of heart-failure in pregnancy, since the prognosis depends so largely on prompt recognition. While estimation of the velocity of blood-flow in all pregnant women is obviously not indicated, the method will be valuable in selected cases.

THE BUDGET

THE Chancellor's speech last Tuesday will do something to revive a confidence badly shaken by the economic crisis. It will be noted abroad that despite our military commitments and social expenditure we can already balance our budget and intend to do so for some years. Mr. Dalton can fairly claim that his proposals strengthen our position, both internal and external, and the only question is whether they will do so sufficiently. As he said, no other country faces so tough an external situation; and the final test of financial measures is their effect on our alarmingly adverse balance of trade. By their concessions on income-tax the Government go some way to restore incentives to harder work: the raising of the maximum for earned-income relief from £150 to £250 will incidentally be of substantial benefit to a large proportion of doctors, and the return of child allowances from £50 to £60 also diminishes the disabilities under which the middle-class parent has been labouring. If Mr. Dalton is right in hoping that increase of tobacco taxation by half will lower tobacco consumption by a quarter, he will have limited the waste of precious dollars on a commodity which we can no longer afford in such quantity. But whether such measures are really commensurate with the need remains to be seen. Before the year is out the crisis may well require more drastic action to check expenditure abroad and induce higher production at home. In particular we may have to devote much more of our efforts and resources to producing food.

WE have to record that Dr. S. Monckton Copeman, F.R.S., died at Hove on April 11 at the age of 85.

SCREENING-OUT THE NEUROTIC

H. J. EYSENCK
Ph.D. Lond.
From the Psychological Department, The Maudsley Hospital

THE experiences of the war of 1914–18 demonstrated the desirability of excluding potential neurotics from the Armed Forces, and in both world wars many different schemes were proposed for effecting such a "screening-out." But the stream of neurotics passing through neuropsychiatric hospitals showed that a selection procedure which had proved successful in the field of intelligence and special abilities failed to grapple with the more intangible problems of emotion, adaptability, and character.

These problems still claim our attention now that the war is over. The likelihood of universal military service, the need to have large forces under arms for a long time to come, and the importance of husbanding man-power in industry generally make essential the development of suitable methods of selection on the temperamental side.

The aim of these methods should not be merely the negative one of preventing the neurotic from being chosen for a position for which he is unsuitable and in which he will break down; a more positive aim might be the selection of neurotics for suitable treatment or for guidance into jobs having a low "stress" value. It is clearly necessary to have valid and quick methods for identifying the neurotic or the potential neurotic; what use may be made of the information gained depends on factors outside the competence of the psychologist or the psychiatrist.

There are two main approaches to this problem: the psychological and the psychiatric. These two approaches have at times been held to be antagonistic, and there are undoubtedly considerable differences between them in methodology and underlying philosophy. Yet, in spite of disagreements, which have at times become vocal (Rodger 1943, 1944, Gillespie 1944), it seems clear that psychology and psychiatry have complementary functions, and have everything to gain by understanding each other's points of view.

The disputes which seem to divide psychologists from psychiatrists are often due to a failure to effect such an understanding. Thus psychiatrists often claim that for screening purposes the traditional psychiatric interview cannot be dispensed with, and that objective techniques have no place as yet in this field. On the other hand, psychologists often draw attention to the subjective nature of the psychiatrist's work and claim that tests developed along traditional lines can fill this important gap.

An extreme development of the psychiatric position is seen in the American practice of having large numbers of recruits seen for five or ten minutes by a psychiatrist who pronounces on their mental fitness on the basis of this brief interview (Wittson et al. 1943). An extreme development of the psychological position would consist in the classification of recruits as "neurotic" on the basis of objective tests alone.

"Screening" is essentially a dual task. In the first place, the extremely large number of recruits or applicants has to be sifted to find as many of the problem cases as possible. As a second step, it has to be decided whether each man is likely to adjust satisfactorily or not. This final decision must be left to the psychiatrist, but the *preliminary sifting* can be done by means of objective psychological tests. In other words, the screening should contain two filters, the wide-mesh psychological filter, and the finer psychiatric filter.

EFFICIENCY OF PSYCHOLOGICAL FILTERS

It is possible to compare the efficiency of diffe psychological "filters" by statistical indices (Hunt et 1944, Eysenck 1945). These indices are constructed on principle that, if a test can distinguish validly betw a group of neurotics and a group of normals, its efficie is a function of the percentage of correct neurotic ide fications and of the percentage of "false positives" i.e., normals diagnosed as neurotics. A simple but formula is the following:

$$\textit{Screening index} = \frac{P - N}{100}$$

where P is the percentage of neurotics correctly diagnosed by the test, and N is the percentage of normals wrongly diagnosed as neurotic by the test. The in varies between the limits of 1 (perfect discrimination) and 0 (no discrimination at all).

With this formula we can compare the efficiency of various psychological "filters," provided the populations tested are roughly similar. This condition appears to be fulfilled in a number of researches, one of which summarised work with three objective psychological tests and one American questionnaire (Eysenck 1945), another used individual interviews given by specially trained women of the W.R.N.S., and interpretations of their findings by psychiatrists (Curran and Roberts 1945), while the third made use of the "Maudsley medical questionnaire," a psychoneurotic inventory which I constructed on the basis of item analyses performed on a number of previous inventories (Eysenck 1947).

In all these researches the validating criterion of "neuroticism," against which the efficiency of the test was measured, consisted in the previous referral of the person concerned to a neurosis centre. The criterion of normality, on the other hand, was simply the failure of the person to be referred to such a centre. In other words, the normal group in each case almost certainly contained several actual or potential neurotics who would sooner or later find their way to a neurosis centre.

The results of comparing the six tests (interviewing, two questionnaires, and three objective tests) are as follows:

Tests	*Screening index*
Maudsley medical questionnaire ..	0·75
Dark vision test	0·63
Suggestibility test	0·55
Interview	0·38
American questionnaire ..	0·36
Ranking Rorschach	0·32

It will be seen that three of the psychological tests are superior to the interview, while the other two are only slightly inferior. All six tests show an efficiency rating which suggests that even in their present undeveloped form they might be useful in detecting potential neurotics. Since the tests in combination are likely to prove much more informative than they are *in isolation*, the figures present a strong prima facie case for further work along these lines. It may also be noted that though the figures quoted cannot pretend to great accuracy in view of the fact that different populations were used in the different researches, they suggest that an objective test, such as the suggestibility test, or a questionnaire, such as the Maudsley one, which can be given in a few minutes to several people at a time, and which does not require great skill in administration or scoring, may be superior to the *relatively complicated* interviewing technique described by Curran and Roberts (1945).

Proof that a test discriminates between normals and acknowledged neurotics is not proof that the test would pick out the potential neurotic *before his breakdown*. Our evidence on this point is only presumptive. Thus, in my work at Mill Hill Emergency Hospital, I found that he tests mentioned succeeded in differentiating the more seriously from the less seriously ill, agreeing well with the psychiatrist's opinion (Eysenck 1947). I also found that in "normal" groups these tests differentiated between the well-adjusted and the less well-adjusted. And in a large-scale experiment on R.A.F. recruits it was found that there was considerable agreement between a psychiatrist's report on the subjects' mental health and likelihood of breakdown, and the subjects' scores on the Maudsley medical questionnaire.

But the need for direct evidence on this point cannot be gainsaid. Such evidence can only be provided by large-scale follow-up studies, and it is one of the main purposes of this paper to draw attention to the need for such an extension of research.

SUMMARY

Attention is drawn to the importance of "screening" methods in military and industrial affairs, and to the necessity of coöperation between psychologists and psychiatrists in this field.

Data are presented to show that objective tests, questionnaires, and other modern techniques are comparatively successful in discriminating between "neurotics" and "normals," and it is suggested that a strong prima facie case exists for the inception of large-scale follow-up studies to investigate the effectiveness of these procedures in screening-out the neurotic.

IMPERIAL CANCER RESEARCH FUND

1946-47

IN his summary of the work done during the past year in the laboratories of the Imperial Cancer Research Fund, Prof. W. E. Gye, F.R.S., the director, reports developments in most of the main lines of investigation.

In the chemical field Mr. H. G. Crabtree, M.SC., has continued his studies of the relation between carcinogenic action and sulphur metabolism. He has already shown that the induction of tumours by the application of carcinogenic hydrocarbons may be retarded by the simultaneous application of compounds interfering with sulphur metabolism, and has demonstrated that there is a parallel between the degree of anticarcinogenic and sulphur-inhibiting activity. If carcinogenic activity depends on the interaction between carcinogen and some sulphur-containing constituent of the cells, then it might be possible by the application of some endogenous sulphur-containing compound to compete with the normal interaction and so nullify it. In an attempt to bring this about Crabtree applied various thiol compounds at the same time as 3 : 4-benzpyrene. Several mono-thiol compounds were tested without effect. Two di-thiol compounds were tested: toluene-3 : 4-dithiol and 2 : 3-dimercapto-proponal (B.A.L.). Both these compounds are chemically extremely reactive. Unfortunately the first proved very toxic and could be used only in relatively small dosages, which were inactive. The compound known as B.A.L. could be given in quite high doses, but again no support for the hypothesis behind the experiment was forthcoming: there was no interference with the carcinogenic action of the benzpyrene.

Another aspect of the relation between cancer and sulphur metabolism is revealed by the fact that normal metabolites of the carcinogenic azo-dyes inhibit the activity of sulphhydryl enzymes. This relation seems to be in the opposite sense to that between the hydrocarbon carcinogens and sulphur metabolism. When the two types of carcinogen were applied at the same time to mice there was no additive effect—in fact, there was some inhibition of the action of the hydrocarbon in one case, but here the azo-compound used (*o*-aminoazotoluene) was somewhat toxic.

Dr. L. Foulds's researches have provided some illustration of the hereditary factor in cancer. He has investigated the action of 2-acetoaminofluorene in different mouse strains by including the compound in the diet. The tumours which resulted differed in their site according to the sex and strain of the mice. In R3 mice tumours of the bladder were produced in males but not in females. This sex difference is not universal, since Armstrong and Bonser did not find it in CBA mice. The treated R3 females developed mammary cancers, as they do spontaneously, but the treatment appeared to accelerate their appearance.

Sidelights on the virus aspect of cancer are provided by Dr. B. D. Pullinger's study of the parts played by œstrogen and milk factor in the development of nodular hyperplasia of the breast which appears in all females of the R3 strain of mice. A subline of this strain free from milk factor was established by rearing an original family with a foster-mother from a cancer-free line. Virgin females of this subline and of normal R3 mice were spayed when 56 days old and were given one or two applications of œstrogen. After these applications there was a progressive development of the mammary glands followed by a regression. This regression in the subline free from milk factor proceeded until at autopsy their mammæ were composed of shrunken ducts without any foci of acinous proliferation, while in the normally reared females there were scattered foci of adenomatous proliferation indistinguishable from those seen under normal conditions of cyclic œstrous phases or pregnancy. The result proves that the appearance of nodular hyperplasia is dependent on the milk factor.

The endocrine factors are implicated in Dr. E. S. Horning's researches. Before the war Horning had initiated an investigation into the possibility of inducing tumours of the prostate by local injections of methylcholanthrene. Tumours were readily produced but they were either sarcomas or squamous-cell cancers and quite unlike those seen clinically. The type of tumour depended on the strain of mice used: all sarcomas were produced in R3 mice and sarcomas and squamous-cell cancers in Strong A mice. Last year Horning took up this study again and was able to produce other types of prostate tumour by a development of Peyton Rous's finding that grafts of embryonal tissue mixed with carcinogen made in homozygous mice grow and develop cancerous properties. Horning found that strips of adult prostate tissue wrapped round a crystal of methylcholanthrene and implanted subcutaneously in homozygous normal mice of the same strain will readily develop into tumours. Again the type of tumour apparently depends on the type of mouse used. In Strong A mice almost all the tumours were glandular cancers, which were transplantable and showed various degrees of secretory activity. All the tumours in C3H mice were spindle-cell sarcomas. These tumours are under active investigation and obviously the method offers great possibilities for the study of the development of glandular tumours and of the direct and indirect effects on them of hormones and other agents.

Another application of the Peyton Rous technique has been made by Prof. Ida Mann, who produced cancers of the lens epithelium by mixing such tissue from young mice with methylcholanthrene and implanting the mixture into other mice of the same strain (C3H). This proves that the *immunity* of the lens from malignant change is not due to any immunity of the tissue itself, but probably lies in its situation in the body and its absence of blood-supply.

There have been several changes in the staff during the past year. Mr. R. J. Ludford, D.SC., Mr. E. S. Horning, D.SC., and Dr. L. Dmochowski have taken up appointments elsewhere. Newcomers are Dr. James Craigie, F.R.S., who should be a strong reinforcement to virus investigation; Mr. P. C. Williams, B.SC., as endocrinologist; and Dr. C. C. Spicer as geneticist.

Reconstruction

THE HOME CONSULTANT

F. HARWOOD STEVENSON
M.D. Lond., M.R.C.P.

ONE of the objects of the National Health Service Act is to extend and improve consultant facilities, so that patients may more readily have the benefit of a specialist's opinion. In arranging this extension, however, we must avoid any unnecessary loss of valuable features of the old dispensation.

Patients unable to pay a consultant's fee have hitherto had to rely either on a hospital or on a "further opinion" given by a kindly colleague or partner of the general practitioner attending them. Even this partial service has been inefficiently distributed throughout the country—difficulties of travel and inaccessibility of outpatient departments often proving insuperable obstacles.

In the new service opportunities for full investigation of patients are to be developed by opening new consultant centres for inpatients and outpatients in areas which are badly served. But in practice the shortage of domestic and nursing staff will make it difficult to extend hospital services. Instead, would it not be possible to bring the consultant to the patient?

Today, when a person is too ill to attend an outpatient department, the general practitioner often sends him into hospital, simply because he feels uncertain of the diagnosis or the treatment. With a consultation at the right moment many of these patients could be looked after at home, which they would usually prefer, and a hospital bed would be saved.

An extension of the system of consultations at hospital also carries the danger that the public may lose what many of them have at present—a doctor with experience and ability to take responsibility, who can enable them to get the best out of the medical services which will be at their disposal. No specialist can take this general practitioner's place; and even a group of specialists, however efficient, implies division of ultimate responsibility. Care from a practitioner, with specialist advice available when necessary, is of more value to the patient, special circumstances apart, than constant specialist direction. The practitioner stands to gain both from the consultations and from his continued responsibility for the patient, and the public gains from this enlargement of his experience.

In practice home consultation works well. I have found no difficulty in collecting at the bedside whatever specimens are required for investigation. The necessary sterile containers, solutions, pipettes, &c., are easily carried, and when appropriate I take with me, in the car, a technician with a portable X-ray apparatus or Cambridge portable electrocardiograph. X-ray photographs—chest films in particular—can be taken while the consultation is proceeding and are developed on return. Specimens are examined, and a telephone conversation with the practitioner usually completes the consultation.

The administrators of the new service would realise a very large saving in hospital beds. This saving would be effected by no second-best method but by one which would maintain for the public the highest standards of general practice.

A SUGGESTION

General practitioners are busy men, and if they are to do all they might for their patients they must have opportunities for acquiring new knowledge. If a general physician were appointed as "home consultant" in each area his contacts with the local practitioners, and his experience of their needs, would enable him to act as a dean of postgraduate studies for the practitioners of the district. Part of the duties of such a man would be to watch the literature; to a discussion groups, lectures, and demonstrations, himself or by specialists; and to pass on advances practical value to the general practitioners, re their knowledge of the less familiar aspects of ge medicine. He should have some beds to keep alive his clinical ability, and the practice of direct responsib

Many general practitioners who fear loss of respo bility and interest in the new service would approv appointments of this sort, and would willingly coöpe with the home consultant in a scheme designed to main and enhance their value to their patients.

Medicine and the Law

Workmen's Compensation—Costs of Visit to Medical Referee

IF a court orders a workman to go and be ex. by a medical referee under the Workmen's Compen. Act, it is difficult to imagine that there could be doubt of the power of the court to allow the man travelling expenses. Yet this question, which the itself ought not to have left in dispute, has occupied turn the Court of Appeal and the House of Lords has been answered differently by these two emin tribunals.

In 1940 a workman named Halliday was seriously injured. His employers recognised that his accident was within the Workmen's Compensation Act and the made him weekly payments on the basis of total inca pacity. In 1945 they had him examined (under section of the Act) by their own doctor, and soon afterwar they notified him (under section 12 (3)) of their intentio to reduce the weekly payments to 15s. on the groun that the incapacity was no longer total. Hallida thereupon sent his employers a counter-notice accom panied by a certificate from his own doctor who sai that the patient was not able to follow his occupatio and that payment on the basis of total incapacity shoul continue. As the doctors differed, the employers aske the county court for an order that the matter be remitte to a medical referee under section 19 (2) of the Act fo a certificate as to Halliday's condition and fitness fo employment. The court made the order and the patien was required to travel some 20 miles on two occasion for the purpose of the examination. The medical refere certified him fit only for very light work. No work o this nature was found for him, and the employers wen on paying on the basis of total incapacity. The county court judge awarded Halliday the costs of his tw journeys which had been undertaken in compliance wit the court's order. The Court of Appeal, by a majorit decision, said that the county court had no jurisdictio to award the travelling expenses, because the employer had throughout made the payments voluntarily an there had been no previous arbitration on a claim b Halliday for compensation. The House of Lords reversing the decision of the Court of Appeal, held tha there was in fact a dispute, that the matter would no have gone to the medical referee unless there had bee an absence of agreement, and that the medical referee in effect, arbitrated between the parties. Consequentl the costs incidental to the reference to the medical referee were within the jurisdiction of the county court.

The country has lately been asked to sanction an increase in the number of lords of appeal in ordinary. It has not been easy to persuade the whole of the legal profession that the judicial members of the House of Lords are at present overworked. The fact that the case of Halliday *v.* Barber Walker & Co. has occupied no fewer than five law lords in the supreme appellate tribunal is perhaps an illustration, rather than an explanation, of the use of our judicial man-power.

Under the auspices of the British Council Sir Alexander Fleming, F.R.S., is lecturing in Vienna on penicillin, and Dr. Robert Cruickshank, director of the central laboratory of the Public Health Laboratory Service, in Poland and Czechoslovakia on the Diagnosis and Control of Infectious Diseases.

In England Now

Running Commentary by Peripatetic Correspondents

I have just been addressing an undergraduates' club ambridge, and thus have renewed my slight acquain- ce with that old town. The chief building is Wool- th's. On my way up from the station I asked a ceman how to get to Sidney Sussex College, and answered "Do you know Woolworth's ?" I said I ected I could find it, and he answered that the college just beyond it on the same side. From his voice's e it sounded as though it were an appendage to it. er I was due to go to Girton and stood in a queue for 106 bus that I had been informed went there; but en it came it was going in the other direction, and I ed the conductor where was the stopping-place on the er journey, and he answered "Do you know Wool- rth's?" This time I could say with some pride, Yes!" "Well," he said, "the stopping-place is just posite."

After Woolworth's there is the Fitzwilliam museum. two favourites there are Sir William Nicholson's Girl with the tattered glove" and Stanley Spencer's of-scape of some red cottages. The first is now splen- lly hung in an alcoved recess. You are standing in the e-Raphaelite room and turn your head to the right, and ere you see her as a winsome little figure, luring you m the far end of the next room. Her features begin stand out clear as you pass the arch between the rooms. ou see a serious but not stern expression which changes a smile as you approach. And then there comes a tle twinkle in her mouth, first on the left side and then, you are half way down the room, with a twitch at the gle of the right. But she never looks at you; the eyes e inscrutable, but there is no glint in them. As you me near to her the smile all fades and is replaced by an estimable sadness. She was not smiling at you but at me happy memory before the glove was tattered or the in, in streaks, was showing through the fur of her coat.

There is also King's College Chapel. Its wonders would e beyond description were it not marred by the screen. o see a great church, stand at the west door and look up the east. There are some that were clearly built to e divided into two, with an inner sanctuary. Not so ing's Chapel. The mind that designed that great work meant it to be viewed as a whole with a vista from end o end. And then some creature of habit persuaded the King there really must be a screen. "Every great church has one." Later the organ was put on it, and the beauty of the sound that comes from it has become a part of the beauty of the stonework. And thus the organ has become a bar to the removal of the screen. Where could they put the organ? I believe it could go underground today, and that acoustic engineers could make it echo through the building as beautifully as when I was there the other day.

* * *

I attended a post-mortem examination the other day in an undertaker's work-room, with the undertaker as an interested spectator. I was remarking on the well-marked "nutmeg" liver when an old surgeon who was present scoffed at this term and complained that we referred in our descriptions to things which these days are seldom or never seen, especially by students. Whereupon the old undertaker produced from his hip-pocket half a nutmeg which had been carefully sawn. He said that he had had this in his hip-pocket for 30 years following the prescription of a gipsy whom he consulted for his lumbago. It had been a most successful and permanent cure.

* * *

If the doctor's bride is to deal adequately with night calls she must appreciate that they differ fundamentally from those in the day, which are called messages. The message impinges on the *personalities* of the doctor and his wife, but the night call digs at their *basic temperaments*. By "temperament" I mean the way the innate neurological set-up gets cracking when a stimulus forces it to respond by getting cracking. This is pretty scientific, but you will grasp what I mean if I describe the two types of response among men when the phone (the stimulus) rings in the middle of the night. To cope with the stimulus and its effects you must know to which of the two types your man belongs.

Primary Type.—As the bedside phone bell jangles, so the nerves and muscles of this type vibrate. With a twitch, jerk, tremble, and oath he is up and at it. Then, after a momentary pause while he grinds the handpiece into the bedclothes and his breathing-rate rises from basal-sleep rate to waking speed, he slams the phone against his ear. He bellows "Hullo, YES!" As he listens he scratches himself in some out-of-the-way place and rubs one foot against the other. "Who? Where? Why, of course. Take me a short while to get along. Hot water. Soap. Towels. 'bye." He dresses, hissing through his teeth.

Secondary Type.—This sort doesn't exactly hear the bell. He reaches for the phone in a cataleptic way like a warm mamba in search of an irritant. He gets hold of the alarm clock and as the phone continues to ring he pushes the clock under the pillow and settles for deeper sleep. At this point your job is to answer the call and at the same time to keep your man awake. This is fantastically difficult, but if you fail he won't be any good for at least an hour. When you have dealt with the call (see previous notes) flood the room with light and keep talking. This will bring him to a sitting position, whereupon you must thump his back violently, repeating with each thump, "Smith, 9, Times Square" (or whatever the address is). As like as not he will answer, "Nine squared equals eighty-one. Ninety-nine, say ninety-nine." But this is progress. He may even stagger out of bed and begin to dress; scratching his head thoughtfully all the time. He may then undress and go to bed again. In psychology this is known as regression. You have been warned and you must forestall it.

After returning from the night call each type has his own characteristics. The Primary will act according to the success or failure of his mission. If successful he will light the fires, bring you tea, keep you awake with sentences beginning, "I've always thought . . .", or recite bawdy rhymes or dawn poems according to his *Kultur*. If he has failed in some aspect of the case he will undress stealthily and, yawning manfully, return to sleep; on waking he will pretend to be as fresh as a daisy. Doctor Secondary, once he has got going, cannot be held back. On his return he will complete the case-notes, write to the *B.M.J.* or to an aunt—in fact, he will continue from where he left off the day before. He will certainly not return to the connubial couch to snatch further warmth and sleep. He does not snatch at anything. Therefore, my dear, do not be unduly miserable the first time this happens. It will only mean that you have married a Secondary Type.

* * *

Not long ago we used to think that a cell of the body, once adult, did not change much. Physiologists used to talk about endogenous and exogenous protein, as though they were quite separate; but now it seems that such a division is artificial, that *all* our body cells are in a state of constant flux, anabolism and katabolism without end. It is not strictly accurate to talk of individual cells, since the cell is never a finite individual even in death, but a chance aggregation of constantly changing basic chemical substances. If one follows this argument to its logical conclusion (a thing philosophers won't do, because they want to know what is logic and what is meant by conclusion), then we are priding ourselves unduly by thinking we are individuals (i.e., undivided and indivisible). We already realise that every person on this earth is dependent on others in some way, and that the aggregate is more important than the individual; but now it seems that we are closer to each other than we thought. Are we not chance aggregations of matter in constant flux? It's a sobering thought.

Reconstruction

THE HOME CONSULTANT

F. HARWOOD STEVENSON

M.D. Lond., M.R.C.P.

ONE of the objects of the National Health Service Act is to extend and improve consultant facilities, so that patients may more readily have the benefit of a specialist's opinion. In arranging this extension, however, we must avoid any unnecessary loss of valuable features of the old dispensation.

Patients unable to pay a consultant's fee have hitherto had to rely either on a hospital or on a "further opinion" given by a kindly colleague or partner of the general practitioner attending them. Even this partial service has been inefficiently distributed throughout the country—difficulties of travel and inaccessibility of outpatient departments often proving insuperable obstacles.

In the new service opportunities for full investigation of patients are to be developed by opening new consultant centres for inpatients and outpatients in areas which are badly served. But in practice the shortage of domestic and nursing staff will make it difficult to extend hospital services. Instead, would it not be possible to bring the consultant to the patient?

Today, when a person is too ill to attend an outpatient department, the general practitioner often sends him into hospital, simply because he feels uncertain of the diagnosis or the treatment. With a consultation at the right moment many of these patients could be looked after at home, which they would usually prefer, and a hospital bed would be saved.

An extension of the system of consultations at hospital also carries the danger that the public may lose what many of them have at present—a doctor with experience and ability to take responsibility, who can enable them to get the best out of the medical services which will be at their disposal. No specialist can take this general practitioner's place; and even a group of specialists, however efficient, implies division of ultimate responsibility. Care from a practitioner, with specialist advice available when necessary, is of more value to the patient, special circumstances apart, than constant specialist direction. The practitioner stands to gain both from the consultations and from his continued responsibility for the patient, and the public gains from this enlargement of his experience.

In practice home consultation works well. I have found no difficulty in collecting at the bedside whatever specimens are required for investigation. The necessary sterile containers, solutions, pipettes, &c., are easily carried, and when appropriate I take with me, in the car, a technician with a portable X-ray apparatus or Cambridge portable electrocardiograph. X-ray photographs—chest films in particular—can be taken while the consultation is proceeding and are developed on return. Specimens are examined, and a telephone conversation with the practitioner usually completes the consultation.

The administrators of the new service would realise a very large saving in hospital beds. This saving would be effected by no second-best method but by one which would maintain for the public the highest standards of general practice.

A SUGGESTION

General practitioners are busy men, and if they are to do all they might for their patients they must have opportunities for acquiring new knowledge. If a general physician were appointed as "home consultant" in each area his contacts with the local practitioners, and his experience of their needs, would enable him to act as a dean of postgraduate studies for the practitioners of the district. Part of the duties of such a man would be to watch the literature; to discussion groups, lectures, and demonstrations, himself or by specialists; and to pass on advan practical value to the general practitioners, ref their knowledge of the less familiar aspects of medicine. He should have some beds to keep alive his clinical ability, and the practice of direct responsib

Many general practitioners who fear loss of res bility and interest in the new service would appro appointments of this sort, and would willingly coö with the home consultant in a scheme designed to m and enhance their value to their patients.

Medicine and the Law

Workmen's Compensation—Costs of Visit Medical Referee

IF a court orders a workman to go and be ex by a medical referee under the Workmen's Compe Act, it is difficult to imagine that there could be doubt of the power of the court to allow the man travelling expenses. Yet this question, which the itself ought not to have left in dispute, has occupied turn the Court of Appeal and the House of Lords has been answered differently by these two c tribunals.

In 1940 a workman named Halliday was se injured. His employers recognised that his ac was within the Workmen's Compensation Act and made him weekly payments on the basis of total pacity. In 1945 they had him examined (under section of the Act) by their own doctor, and soon afte they notified him (under section 12 (3)) of their int to reduce the weekly payments to 15s. on the g that the incapacity was no longer total. H thereupon sent his employers a counter-notice panied by a certificate from his own doctor who that the patient was not able to follow his occupa and that payment on the basis of total incapacity sh continue. As the doctors differed, the employers the county court for an order that the matter be remi to a medical referee under section 19 (2) of the Act a certificate as to Halliday's condition and fitness employment. The court made the order and the pati was required to travel some 20 miles on two oc for the purpose of the examination. The medical ref certified him fit only for very light work. No work this nature was found for him, and the employers on paying on the basis of total incapacity. The count court judge awarded Halliday the costs of his t journeys which had been undertaken in compliance wi the court's order. The Court of Appeal, by a majori decision, said that the county court had no jurisdicti to award the travelling expenses, because the employ had throughout made the payments voluntarily and there had been no previous arbitration on a claim by Halliday for compensation. The House of Lords, reversing the decision of the Court of Appeal, held that there was in fact a dispute, that the matter would not have gone to the medical referee unless there had been an absence of agreement, and that the medical referee, *in effect, arbitrated between the parties.* Consequently the costs incidental to the reference to the medical referee were within the jurisdiction of the county court.

The country has lately been asked to sanction an increase in the number of lords of appeal in ordinary. It has not been easy to persuade the whole of the legal profession that the judicial members of the House of Lords are at present overworked. The fact that the case of *Halliday v. Barber Walker & Co.* has occupied no fewer than five law lords in the supreme appellate tribunal is perhaps an illustration, rather than an explanation, of the use of our judicial man-power.

Under the auspices of the British Council Sir Alexander Fleming, F.R.S., is lecturing in Vienna on penicillin, and Dr. Robert Cruickshank, director of the central laboratory of the Public Health Laboratory Service, in Poland and Czechoslovakia on the Diagnosis and Control of Infectious Diseases.

1924). Theodor Puschmann's *Geschichte des medicinischen Interrichts* (1889), of which an English translation ras later published, included a comparative study of ontemporary medical education extending to nearly 00 pages.

As reference to your early volumes would show, medical ducation in England has been the subject of active and lmost uninterrupted discussion since the beginning of the 19th century. The bulky parliamentary *Report from he Select Committee on Medical Education* (1834) may be regarded as the first comprehensive English survey of its subject and as the most substantial material expression of that growing dissatisfaction with the medical curriculum which was to culminate belatedly in the Medical Act of 1858. The seamier side of medical education before the passage of the Act is depicted with great penetration and wit in the series of articles anonymously contributed by Albert Smith to the first volume (1841) of *Punch*, under the title "The physiology of the London medical student." The article (p. 201) describing a session at a crammer's class is particularly to be recommended.

The study of the literature on medical education leaves the impression that, as with medicine itself, diagnosis is usually considerably in advance of treatment, and that one of the causes of the sluggishness with which long-overdue reforms have been introduced over the past century is that there has often been a direct pecuniary interest in the perpetuation of anomalies.

In 1912 Abraham Flexner commented that in England "examination is a national industry, getting examined a national habit." Surveying the subsequent growth of special diplomas, an observer today might conclude that the equivalent of an industrial revolution has since occurred in the field of medical education.

In conclusion, the author of these remarks must confess his own lack of academic distinction and disclaim the least pretension to speak authoritatively on medical education. As a student, he found that the medical curriculum offered poor competition to other intellectual pursuits, and he contented himself with passing the qualifying examinations of two medical corporations. Any interest he may subsequently have acquired in medicine he regards as the product of self-education. In fairness to the two medical corporations through which he gained admission to the medical profession, he would insist that they are entirely innocent of any responsibility for any defects of his medical education, as he cannot recall any closer official connexion with them than the payment of examination fees and the welcome intimation that he was respectively their member and licentiate.

Worth, Sussex. N. HOWARD-JONES.

EXPERIMENTAL TUMORIGENESIS

SIR,—Referring to your editorial of Nov. 30 on the work of Professor Lipschutz, may I call attention to my experimental studies in guineapigs antedating Lipschutz by several years? We found that intraperitoneal administration of alkaline anterior-pituitary extracts or intramuscular implantation of bits of anterior-pituitary substance produced hyperplasia and metaplasia of the epithelium of the uterine cervix, with epithelial downgrowths extending deeply into the connective tissue. Papillary tumours of the parietal peritoneum, as well as hyperplastic phenomena in the connective tissues of the tube and the uterus, were observed (*Amer. J. Obstet. Gynec.* 1934, 27, 633; *J. Obstet. Gynæc.* 1939, 46, 232). The peculiarity of the structures of mesodermal origin of the female generative organs—to react to the stimulus of an overactive anterior pituitary, and in turn to the thus generated oversupply of œstrogens, with hyperplastic lesions—was duly stressed. No ætiological connexion, however, between the development of uterine fibroids and œstrogenic overstimulation seems to be clearly demonstrated.

Lipschutz's finding that many months elapsed before any hyperplastic lesions in the uterine wall occurred points to the *anterior pituitary*—which is well known to develop hyperplasia and even adenoma in the wake of long-continued administration of œstrogens—as the factor responsible for localised or universal growth phenomena in the uterine wall.

Cincinnati, Ohio, U.S.A. J. HOFBAUER.

AMYLOID MACROGLOSSIA

SIR,—The interesting case of atypical amyloidosis described by Dr. Margaret Baber (Feb. 8), a condition first described on the Continent by Lubarsch,[1] is almost identical with a case I saw in a man, aged 53, who died from heart-failure, thrombosis, and infarction of the lungs. Almost half the heart in this case was amyloid (fig. 1). The tongue (fig. 2), œsophagus, skin, and walls of many of the smaller arteries and veins were also involved, and hæmorrhages had occurred after palpation or other minor injuries to the skin.

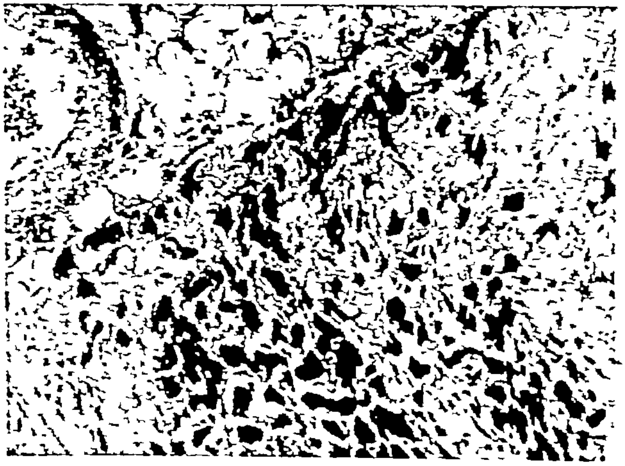

Fig. 1—Section of heart muscle, showing amyloid deposits (grey) between muscle-fibres (black) and in the wall of a blood-vessel. (Masson ×115.)

The pathological proteins, called paraprotein by Apitz,[2] are produced by plasmocytoma cells. One of these proteins is the Bence-Jones protein, which is excreted rapidly in the urine. Paramyloidosis is not due to Bence-Jones proteinæmia, but the same tumour cells that produce Bence-Jones proteinuria also produce other different pathological proteins which involve the tissue of the tongue, heart, and walls of the blood-vessels, and other muscles. The plasmocytosis can be localised to one or several parts of the body, as in multiple myeloma, or spread all over it, as in diffuse plasmocytosis. In some cases the tumour cells cannot be found, because the degenerated area is too small and the pathological plasma cells can occur in any part of the body and may not be recognised. This seems to have happened in Dr. Baber's case and in mine.

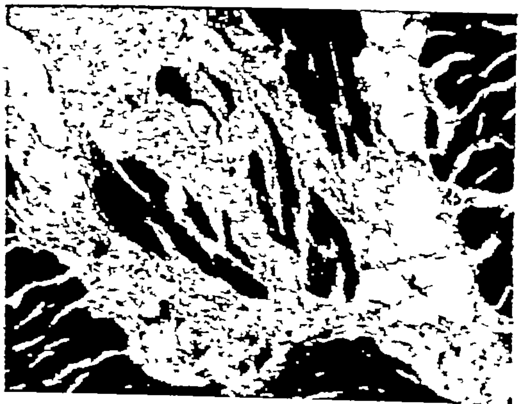

Fig. 2—Section of deeper layers of tongue, showing muscle bundles (black) and amyloid deposits (grey). (Masson ×115.)

Luisenhospital, Aachen, Germany. RUDOLF ENGEL.

Letters to the Editor

HÆMOLYTIC DISEASE OF THE NEWBORN

SIR,—I read with great interest the annotation in your issue of April 5 on the prognosis in what I am sorry to see you still call erythroblastosis fœtalis rather than hæmolytic disease of the newborn. I am not convinced that what Wiener himself has called the "formidable procedure" of exsanguination transfusion presents any advantages over simple transfusions with Rh-negative blood in amounts required to correct the degree of anæmia. Exsanguination transfusions would be more than justified if damage to the liver and brain could thereby be prevented, and although Wiener claims that they do prevent kernicterus there is no evidence that the products of hæmolysis ever produce such damage. Indeed, the evidence is all to the contrary; for instance, changes in the liver and brain have never been described in congenital anæmia of the newborn in which the degree of hæmolysis is greater than in icterus gravis, nor do the investigations by my colleague Dr. Baar bear out Wiener's view that these changes are due to the blocking of vessels with agglutination thrombi. The changes in these organs are almost certainly due to the action of the maternal antibody on the cells of the liver and, either directly or indirectly, on the brain-cells. It is possible that a small part of this antigen-antibody reaction occurs after birth, and therefore might be checked by exsanguination transfusion, but the greater part takes place before birth—a fact which is proved by the high proportion of stillbirths in the obstetric history of the mothers of these children, the not infrequent presence of icterus at birth, the occurrence of hydrops fœtalis, and the finding by Boorman and Dodd of the Rh antigen in the fœtal tissues.

Although the prognosis after treatment with Rh-negative blood falls far short of Gimson's claims for it, it is certainly better than you suggest. At the Birmingham Children's Hospital we now have records of 274 cases treated since 1931. From 1932 to 1936 intramuscular injections of serum were at first used, and later transfusions with blood in which regard was paid only to the ABO grouping in a group of 44 children with a resultant mortality-rate of 52%. From 1939 to 1941 blood-transfusions with compatible ABO groups only were given and the mortality-rate was almost unchanged, being 50·5% (66 children); but from 1942 to 1946 Rh-negative blood of the infant's blood group or of group O was used and the mortality-rate in a group of 163 children was reduced to 29·3%. Records of mortality-rates by other writers before the era of Rh-negative blood varied from 46% to 75%, and the only other series of cases treated by Rh-negative blood with which I am familiar is one by Snelling, of Toronto, dealing with 60 children. He found that his survival-rates were not increased by its use, although he has recently had excellent results in a small series of 17 cases when he gave a series of plasma "drips" in addition to the Rh-negative blood.

Clearly therefore, even when Rh-negative blood is used, the mortality is a severe one, and there is no doubt that you are right in saying that good results are only likely to come from treatment which will prevent the formation of Rh antibody by the mother or its passage across the placenta to the fœtus; moreover, such treatment will also prevent kernicterus which at present occurs in a proportion, variously estimated at 5 to 15%, of the survivors.

Birmingham. LEONARD G. PARSONS.

REST AND PROGRESSIVE RELAXATION

SIR,—Last year (1946, i, 440) you published a letter from me on the recuperative effects of rest and neuromuscular relaxation, and on the method of suggestion and deep breathing whereby relaxation may be produced.

For the sake of completeness I should now like to add that I have discovered, after many years' experience, that the maximum effect of deep breathing in producing physical and mental relaxation is attained by holding the breath for a fraction of a second after a normal effortless *expiration*. Holding the breath for a brief moment after *inspiration* is well known as a method of enhancing efficiency—e.g., in climbing—by increasing the oxygenation of the blood; and it is a potent factor in the b effect of the Yogic method of "interrupted bre (*pranayama*). But the beneficial effect which I observed, in myself and in my patients, of a pau expiration has a different physiological basis. A of profound quietude, akin to if not identical wit hypnosis, seems to be in my own case the inv result, and may mark the progress of the neurom relaxation from the voluntary muscles of the system to the *involuntary muscles* of the v digestive, and respiratory systems, and so on t sympathetic nervous system itself.

The method can be exceedingly potent in b anxiety and relieving mental and nervous tensio

London, W.1. WILLIAM BRO

PLASTIC EYES

SIR,—The statement in your annotation of M (p. 379) that "the iris is painted on paper and porated in the eye behind a layer of clear resin" be refuted. Eyes have been, and probably still are, in this way, but the most satisfactory results are o only when the eye is "all plastic" and no use is non-acrylic substances alien to the methylmeth and invariably antagonistic to complete fusion.

Your statement that plastic eyes are somewhat than glass ones needs qualifying. Plastic substan lighter than glass, but, while a glass eye of the or reform type is hollow, the plastic eye is soli therefore heavier. Comparison of weight between and plastic shell eyes, however, shows plastic eyes lighter. We have made hollow plastic eyes on the principle but these have many disadvantages, the of which is that they are not easily altered.

With regard to price it should be pointed out th manufacture of artificial eyes made entirely of bristles with difficulties which cannot be app without close acquaintance with the vagaries of comparatively new substance. It is these many v and unappreciated difficulties which make the produc of a plastic eye much more expensive than a glas Moreover, it is unfortunately a fact that much technical skill is required for making plastic eyes t glass eyes.

London, W.1. THEODORE HAMBLIN LTD.

REFORM OF MEDICAL EDUCATION

SIR,—In his extremely interesting account of revision of the anatomical curriculum at Birmin University (March 29), Prof. S. Zuckerman says that t ventilation of the problem of the reform of medi education by the Goodenough Committee "represents last of a series of reviews which started in 1925 wi Abraham Flexner's comparative study of med education."

This reference may possibly lead some readers overlook Flexner's earlier and far more detailed stud of *Medical Education in the United States and Canad* (1910) and *Medical Education in Europe* (1912), whic were published as Bulletins 4 and 6 of the Carne Foundation. These monumental studies still remain the main source of information on modern medical educati considered in its historical and comparative aspects, Flexner's later *Medical Education* (1925) largely repre-senting the essence of the earlier volumes. It is questionable whether later reviews of medical educatio contain any important conclusions that were not expressed or implicit in Flexner's pioneer studies, and it is perhaps worth pointing out that these studies were the work of a layman.

Another survey of earlier date than 1925 is Sir Georg Newman's memorandum to the president of the Boa of Education—*Some Notes on Medical Education in England* (1918)—which, despite its modest title, occupi 124 pages. This was followed by the same author's memorandum to the Minister of Health, *Recent Advance in Medical Education in England* (1923).

It seems appropriate to mention also Theodor Billroth's *Lehren und Lernen der medicinischen Wissenschaften* (1876), the importance of which may be judged from the publication nearly fifty years later of an English transla-tion, with an introduction by William H. Welch, under the title *The Medical Sciences in the German Universities*

024). Theodor Puschmann's *Geschichte des medicinischen nterrichts* (1889), of which an English translation as later published, included a comparative study of ntemporary medical education extending to nearly 0 pages.

As reference to your early volumes would show, medical lucation in England has been the subject of active and lmost uninterrupted discussion since the beginning of he 19th century. The bulky parliamentary *Report from le Select Committee on Medical Education* (1834) may be egarded as the first comprehensive English survey of its ubject and as the most substantial material expression f that growing dissatisfaction with the medical curriculum which was to culminate belatedly in the Medical Act of 1858. The seamier side of medical education before he passage of the Act is depicted with great penetration and wit in the series of articles anonymously contributed by Albert Smith to the first volume (1841) of *Punch*, under the title "The physiology of the London medical student." The article (p. 201) describing a session at a crammer's class is particularly to be recommended.

The study of the literature on medical education leaves the impression that, as with medicine itself, diagnosis is usually considerably in advance of treatment, and that one of the causes of the sluggishness with which long-overdue reforms have been introduced over the past century is that there has often been a direct pecuniary interest in the perpetuation of anomalies.

In 1912 Abraham Flexner commented that in England "examination is a national industry, getting examined a national habit." Surveying the subsequent growth of special diplomas, an observer today might conclude that the equivalent of an industrial revolution has since occurred in the field of medical education.

In conclusion, the author of these remarks must confess his own lack of academic distinction and disclaim the least pretension to speak authoritatively on medical education. As a student, he found that the medical curriculum offered poor competition to other intellectual pursuits, and he contented himself with passing the qualifying examinations of two medical corporations. Any interest he may subsequently have acquired in medicine he regards as the product of self-education. REVACCINATION IN ADULTS

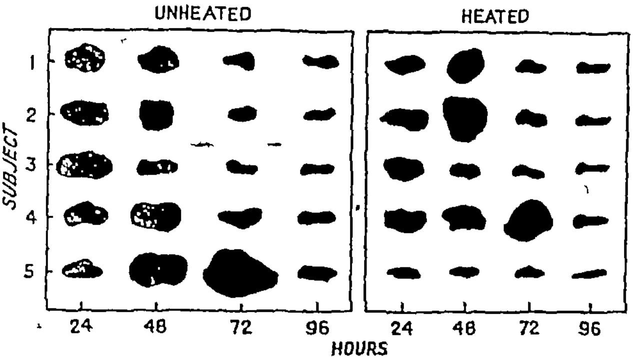
SIR,—*Dr. J. C. Broom's paper (March 22) prompts* us to report some observations made in the Middle East in 1945.

Lieut.-Colonel (now Professor) R. S. Illingworth had pointed out to us that a typical "reaction of immunity" was evoked by a heat-killed vaccine. To verify his statement a series of 20 previously vaccinated patients were revaccinated with both heated and unheated vaccine by a standardised technique with a single scratch 1 cm. in length. The response to both heated and unheated vaccines was similar in each case and had the characteristics of the "reaction of immunity." In a second series of 20 cases where the areas of erythema were plotted no constant differences between reactions to heated and unheated vaccine could be demonstrated. The figure shows the findings in 5 representative cases.

To prove that the virus had been killed, material from the same batch of heated vaccine was used to vaccinate 10 *previously unvaccinated infants. In no case* did a reaction occur; later these infants were successfully vaccinated with unheated vaccine. Intradermal tests on rabbits also showed that living virus was no longer present after heating.



Areas of erythema after vaccination with unheated and heated vaccine lymph.

As calf-lymph vaccine had been employed in these experiments the agents possibly responsible for the reactions were bovine protein, contaminant bacteria, the preservative added to the vaccine, or the proteins of the virus bodies themselves. A series of 10 previously vaccinated patients were accordingly revaccinated with heated vaccine, unheated vaccine, bovine serum, and the preservative. Reactions were noted only with the first 2. Dr. Dennis, of the American University of Beirut, kindly supplied us with vaccine prepared by culture on chick-embryo membrane, the bacterial content of which was negligible. In 10 previously vaccinated patients similar "reactions of immunity" were obtained to this vaccine both when heated and unheated. From these observations we concluded that the "reaction of immunity" was an allergic response to the proteins of the virus bodies in an individual sensitised by previous vaccination.

Circumstances had prevented us from reading the relevant published work; but at this stage we discovered that similar observations had been made in 1901 by von Pirquet, who had reached the same conclusion. We therefore pursued our somewhat naïve investigations no further, believing that we had been in ignorance of *facts well known to better-qualified workers in this* field.

If our conclusions were correct it followed that the "reaction of immunity" in fact only indicated that the patient was immune to variola when the vaccine employed was known to be potent and viable. This explained our previous experiences of seeing patients in whom we had ourselves noted a "reaction of immunity" develop fatal smallpox within two months of vaccination.

Dr. Broom is clearly aware of the problem, but he has noted a considerable number of cases in which unheated lymph gave a "reaction of immunity" while heated lymph gave no reaction. Our experience was different from this: in a few a "reaction of immunity" was given by unheated, but not by heated, lymph; in about an equal number the reverse was noted. We attributed these discrepancies to faults in our technique, and tion, by producing similar reactions with both heated unheated lymph, confirmed our view. Dr. Broom that the reaction to heated lymph may "closly simulate that to unheated; we concluded that the two indistinguishable. We share his uneasiness about *fication; on several occasions* we have seen the of security engendered by a "reaction of i prove disastrously false.

CHEST DISEASE IN RAND MINERS

SIR,—In their letter of Feb. 8 Dr. Frazer and Dr. Walker rightly say that we have a miniature rad plant at the Witwatersrand Native Labour Ass Hospital, which has now been in operation for years. (Like them, we consider that our miniatures of a very high standard, as also are the large X-ray films taken to check the abnormalities seen in the miniature radiographs.) They were wrongly informed, however, that native workers suffering from phthisis may continue *to work if they choose to do so. No native mine labourer.* found to be suffering from pulmonary tuberculosis and/or silicosis is allowed to continue working at the mines; he is compensated and repatriated at the expense of the mines. The compensation paid is, for silicosis, a sum equal to 36 times the amount of his monthly earnings, or £180, whichever of the two amounts is the greater. Similar compensation is paid for pulmonary tuberculosis where the labourer has been engaged in a dusty mining occupation for 8 or more years. Where the labourer is found to be suffering from pulmonary tuberculosis after *having worked in a dusty occupation for 30 days* or longer, he is given an amount equal to 20 times the sum of his monthly earnings, or £100, whichever of the two amounts is the greater.

Dr. Frazer and Dr. Walker add that "during a brief visit to the W.N.L.A. Hospital, no case of chest disease was seen." This seems strange, as we detain a large number of patients in hospital for sputum tests and other *investigations. Apart from these, all patients on the* mines who are suspected to be suffering from pulmonary tuberculosis and/or silicosis, after X-ray, clinical, or sputum investigation, or loss of weight, are sent to our hospital and detained here for examination by the medical officers of the Silicosis Medical Bureau, with a view to possible compensation.

Witwatersrand Native Labour Association, Ltd., Johannesburg. FRANK RETIEF
Chief Medical Officer.

BETTER CARE FOR THE HOMELESS CHILD

SIR,—Your annotation of April 5 suggests that there is fairly general agreement with the recommendations of *the Curtis Committee.* But it is in fact surprising that more written protests have not appeared from workers in public-health, medical, and educational circles considering the extent of the disagreement which exists. The largest single group of children mentioned in the report is that in public-assistance institutions. *It is remarked with* surprise that 60% of these children are short-stay admissions—e.g., children admitted because the mother is having a baby. To this extent the total figures are inflated, for this group can hardly be described *as* "deprived children." The committee consider *that* more accommodation for these short-stay children *is badly needed,* although they remark that there was ample accommodation in children's homes generally before the war. The overcrowding of the public-assistance institutions, therefore, seems to have developed with the war, when women were encouraged to send their children (even those of 2 years) into institutions while they either went to work or had a baby, and there was little warning to the mother that it might have a bad effect on the child's *emotional development.* The legacy of 5000 homeless evacuees tells its own *tale.* Some propaganda in reverse to emphasise the importance of keeping the child in its own or a relative's home where this is at all possible might now *be instituted,* with a quotation from the Curtis report on "the extreme seriousness of taking a child away from even an indifferent home." To a young child even two weeks is a long time.

The Government's decision to make the Home Office e responsible central department is itself remarkable, nce, of the three central departments concerned, this the only one without adequate trained visiting staff the local-authority level.

At a guess I should say the visiting of individual ildren for fostering, adoption, and boarding-out will ntinue to be done by the same people who do it at resent—namely, health visitors, school nurses, and school-ttendance officers, with the added complication that r this part of their work they will apparently be sponsible to the Home Office through the children's fficer. The Curtis Committee propose that this officer hould be an important administrative official of the ouncil, not on the staff of any other department, with pproximately 500 children under her care. As it will not e practicable for her to know and keep in touch with hem all (although the personal touch is the main argu-nent for her appointment) she will allocate groups of hildren to her subordinates. A boarding-out visitor is o be responsible for the supervision of 100–150 children, ach to be visited at least once in three months. She s to be a superior visitor (? a psychiatric social worker)—not a mere health visitor—and this may explain why she is apparently only to do two or three visits a day. Yet health visitors have at least 1000 children to visit, and local authorities have found it almost impossible to fill vacancies because of the shortage. Are psychiatric social workers more plentiful ?

Whether one agrees or disagrees in principle with the recommendations of the Curtis report the main single criticism is that it considers the matter as if in a vacuum. It ignores the fact that there is a shortage in almost every sphere of trained professional women. The inspecting staff of the central government department must be increased, children's officers must be appointed. But where will they be drawn from ? Health visitors, nursery-school teachers, psychiatric social workers, matrons—all are in desperately short supply. Thus we are faced with an increase at the supervisory and inspectorial levels, with a resulting decrease in the already overworked staffs who do the spadework.

Woodford Green, Essex. HILDA MENZIES.

SAND-FLY FEVER

SIR,—The article of April 5 by Dr. John Fleming, Major Bignall, and Captain Blades was of great interest to me as I witnessed a large series of similar cases in a military hospital in Athens during the summer of 1941.

These cases were considered not to be true sand-fly fever for three reasons: (1) the almost clock-like regularity of three days' duration which characterised the outbreak and which is not typical of sand-fly fever ; (2) the absence of really severe headache, which is certainly present in genuine sand-fly fever ; and (3) the absence of the well-known depression and asthenia which characteristically follow sand-fly fever.

The Greek doctors, who are used to these epidemics, have named it the three-day fever ; and it was their opinion that it was not due to the sand-fly. One suggestion made at the time was that it was an abortive form of anterior poliomyelitis, of which there was a concurrent epidemic. The outbreak also coincided with the sea-bathing season.

I suggest that among cases of short-term pyrexia which tend to be labelled sand-fly fever there is a separate entity—" P.U.O., three-day type "—of whose ætiology we are at present ignorant. To label such cases sand-fly fever is to hinder progress.

Brighton. EDWARD W. LINDECK.

SIR,—The review by Fleming, Bignall, and Blades must have evoked wistful memories in those of us who gave some minutes every summer night to hunting in the folds and corners of the mosquito-net for the elusive and diaphanous flies, only to wake on the morrow and find that quite a few had escaped our search and were now showing up all too easily by the large red blob of our blood in their bodies.

The sand-fly set us a nice problem in differential diagnosis. When a fairly large outbreak of sand-fly fever began in Greece, at a time when everybody was acutely smallpox-conscious, 3 cases of ?smallpox were admitted to the isolation ward of our hospital. Their history was one of a three-day fever, and they showed a petechial rash, most marked over the feet, including the soles, and less marked over the legs, hands, and face. The history and the distribution of the rash were in fact reminiscent of smallpox, but the rash was quite superficial and slightly irritating and itching. Our diagnosis of sand-fly fever and insect bites, probably caused by the phlebotomus, was borne out later in this outbreak when we saw a considerable number of similar cases with petechiæ over exposed parts of the body. We never saw weal formations in the patients exhibiting petechiæ.

The admission of ?smallpox cases was of course known to our higher administrative authorities, who, rightly conscious of their responsibility, were not so easily persuaded to regard these cases lightly. There were a number of consultations with Army authorities and Greek medical notables. In fact we were much in the limelight for some days and gained an interesting experience, at the cost of some disruption of communications to our " smallpox-infested " community.

London, W.1. P. F. MEYER.

STEVENS-JOHNSON SYNDROME

SIR,—The Commission on Acute Respiratory Diseases of the U.S. Army Medical Corps,[1] reporting 6 cases of Stevens-Johnson syndrome and inoculation studies from necropsy material of a 7th, emphasise the frequency of lung lesions closely resembling primary atypical pneumonia ; in 2 of their 3 pneumonic cases cold agglutinins were present in significant titres. They cite J. H. Stanyon and W. P. Warner,[2] who in a series of 17 cases found non-bacterial pneumonia in 14, with 2 fatalities showing widespread pulmonary consolidation with a mononuclear-cell exudate.

The disease, which is fairly uncommon, seems to come in small epidemics. Hebra,[3] who as early as 1860 noted its association with pneumonia, thought that it was commonest in April–May and October–November ; and Keil [4] reports that it is not rare in New York City during spring and autumn. That there may be no severe cases for years at a time is suggested by the absence of any example of it in Jonathan Hutchinson's *Archives of Surgery*, which are a good source of reports on unusual dermatological conditions in the 1890's.

Dr. Nellen (March 15) correctly quotes Rosenberg and Rosenberg as alleging that the first cases were described in 1822 by Alibert and Bazin. The Rosenbergs give as their source a thesis,[5] which I have so far been unable to trace ; but as Bazin in 1822 was at the tender age of 15 it seems that the Rosenbergs made a slip. Looking through Alibert's *Monographie des Dermatoses*,[6] I did not find anything relevant to the subject ; but Bazin's hydroa vésiculeux [7] most probably relates to the condition.

Without having a special grudge against eponymous titles I feel this particular one is unwarranted. In his scholarly paper Keil [4] discusses contributions to this subject back to 1860 ; perusal of it will dispel the belief that Stevens and Johnson contributed something essentially new. The Commission on Acute Respiratory Diseases also consider that this eponym has no historical justification.

None of the many terms used for it is wholly satisfactory. Hebra coined the term " erythema multiforme exudativum," all his cases having had only cutaneous manifestations. Later writers have often used terms according to the local signs (dermato-stomatitis ; gingivo-stomatitis ; atypical ulcerative membranous stomatitis ; mucosal respiratory syndrome). Even the more embracing term, " muco-cutaneous fever," is not ideal, for there may be no fever and tissues other than skin and mucous membranes may be involved. Hebra's original term is still more often used than others by authors describing cases with extra-cutaneous manifesta-

tions; compromising on it may help to bring home that skin lesions are often only part and parcel of a systemic disease.

Bethnal Green Hospital, London, E.2. HERBERT LEVY.

SIR,—The publication of three or four communications on the so-called Stevens-Johnson syndrome will certainly stimulate interest in this condition. Some years ago, having become acquainted with the disease, I extracted the literature fairly widely; and I find that the records, including my own, cover some seventy cases, excluding others less well defined and a hundred-odd cases noted by one author in an epidemic. I have not published any account of the disease as it would be too long.

To anyone who has once seen a full-blown case the clinical picture remains unforgettable; faced with a case for the first time, the medical man will surely be baffled.

Some of my tentative conclusions, based on my own observations and a study of all the published cases, are that: (1) while perhaps the majority of cases manifesting this syndrome run true to type, there may be many variations, including for instance the condition referred to by Forman and Whitwell [1] in an article on the association of herpes catarrhalis with erythema multiforme; (2) the syndrome, which occurs more commonly in sporadic form, may also occur in small groups or even in epidemics; (3) there is often an association with some other disease, such as pneumonia; (4) recurrences are sometimes seen; (5) the so-called Stevens-Johnson syndrome belongs to or is part of the condition called erythema multiforme; (6) the evidence points to erythema multiforme and this syndrome as originating in a virus infection rather than an allergic state as has been suggested; and (7) it might be a pity if the syndrome's present designation were perpetuated. Stevens and Johnson wrote in 1922, whereas there are descriptions of the condition certainly as far back as 1896.

London, W.1. HUGH S. STANNUS.

SIR,—Dr. Nellen and Dr. Murray by their papers have aroused considerable interest in the Stevens-Johnson syndrome, partly because they have cleared away the fog around certain rare cases and partly because they, and others, have underlined the comparative rarity of English case-reports, though in America the condition seems to be fairly well known. Because of this I would like to record a further case which at the time it was seen was diagnosed as erythema multiforme bullosum with pneumonia and rheumatic carditis.

The patient was a girl, aged 13, who had been healthy except for growing pains during 1945. She was admitted to hospital in May, 1946, under the care of Dr. C. N. Armstrong, having been ill for three days with left-sided chest pain, sweating, shivering, and general weakness. She was breathless but had no cough or sputum; and on examination she looked ill, with an increased respiration-rate and slight cyanosis. There was limited movement over the left lower chest with impaired percussion-note over both lung bases and an area of tubular breathing over the left lower lobe. A loud systolic murmur was heard at the cardiac apex. Urine was normal. The electrocardiograph showed no significant abnormality, and chest X ray showed a shadow in the lower left axillary region. Blood-count: red-blood cells 4,780,000 per c.mm.; hæmoglobin 88%: colour-index 0·92; white-blood cells 11,300 per c.mm. Some sputum obtained a few days after admission showed no significant abnormality.

For the next ten days she continued, despite treatment, to run a temperature up to 103·8° F, with chest signs; then a patchy erythematous rash appeared on her arms, legs, and trunk, becoming deeper in colour, confluent, and vesicular on the limbs. Her mouth and tongue showed ulceration, and her eyes moderately severe conjunctivitis. During the next day or two the rash became bullous, and the mouth lesions more extensive. The temperature rose to 104·8° F, and the general condition deteriorated.

Five days after the appearance of the rash, her condition, which had been very poor, suddenly improved; the temperature dropped to normal, the rash gradually faded, and the skin peeled in places, leaving a mild pigmentation which rapidly cleared. The mouth lesions quickly healed, and the conjunctivitis improved. From this time on her condition gave rise to no further anxiety, and she was discharged a month after admission.

A blood-culture taken at the height of the erupti sterile, and a chest X ray taken at the same time sho lung fields to be almost normal, while the white-cell was 6100 per c.mm. (polymorphonuclear cells 66%, l cytes 26%, monocytes 2%, eosinophils 5%, degenerate 1%). The urine showed no abnormality, and specimens of sputum were negative. A further full examination during convalescence was normal.

Treatment with penicillin and sulphamethazine was throughout the illness, but had no effect on the although it may have prevented secondary skin infection.

I saw this patient again on March 27, 1947. She was well and had had no recurrence of the condition. Her eyes, and mouth were normal. There was an apical murmur, but no radiological evidence of cardiac or disease, and her blood-count and film were normal.

This case seems to illustrate Dr. Sneddon's ment concerning the association of the syndrome atypical pneumonia.

University of Durham.

First assistant to the Depa of Medicine.

ESTIMATION OF PENICILLIN IN SERUM

SIR,—In my letter last week I described a modifi of the micro-method for penicillin assay, using D tubes. The directions should read:

> Starting with two drops of the serum to be assayed two drops of 1% glucose peptone water and An indicator, doubling dilutions are made on paraffined The last two drops are discarded. (A control, of is put up as well.) The final two drops of each dilution inoculated with the Oxford staphylococcus and int by means of a Pasteur pipette into sterile Dreyer's tubes.

Cotton-wool plugs can be used in the Dreyer's tu instead of sealing them with 'Plasticine,' without noticeable diminution in the volume following incubatio

General Hospital, Birmingham. M. J. PIVAWER

AGE AND SEX DISTRIBUTION OF DIPHTHERI

SIR,—*In his interesting paper on diphtheria in* Olde burg, Germany, in your issue of March 29, Colo Walker records the preponderance of female cases (especially in those over fifteen years of age) and high incidence among adults relative to children. *says that the German medical officers of health* exp both of these features by reference to artificial immunisa tion of children. I agree with Colonel Walker that it is questionable whether this explanation is wholly adequate.

In a study of the epidemiology of diphtheria in Dublin *over a long period* [1] I noted, like Colonel Walker, the preponderance of female cases. Of his 3538 cases, 2296, or 64·9%, were females. Among 6261 cases notified in Dublin in the years 1935–42, females numbered 3474, or 55·4%; and among the 1012 cases aged fifteen years *and over females numbered* 723, or 71·4%.

More striking, perhaps, is the high incidence found by Colonel Walker among those of fifteen years and over—60·9%. Between 1933 and 1942 the average incidence in Dublin in those of fifteen years and over was only 16·4%.

I also showed how over a period of years the incidence of the disease might steadily shift from a lower to a higher age-group, as it did between 1928 and 1937. This shift was accompanied by an increase in severity, as shown by analysis of the fatality-rates according to *age-groups.*

A decline in general incidence, as observed in Dublin, coincided with a decline in general severity *and a shift* in incidence to the lower age-group—i.e., 0–5 years. This decline in incidence happened to accompany an *intensified artificial*-immunisation campaign, the decline being maximal about 1941. The decline, however, was almost certainly not related to immunisation, because it could have been foreseen from the fluctuations in incidence in Dublin since 1801. Since that time there had been fairly uniform cyclical variations, with ten-yearly peaks. Further, the *age-distribution* of the cases in 1940–41 was comparable with that of the years 1929–32, a period before the introduction of immunisation in blin. Such variations in severity and age-incidence ve been observed by Deicher and Agulnik[2] and by ers. They were observed even before *C. diphtheriæ* s discovered.

---

[1] *Irish J. med. Sci.* 1943, pp. 97, 140.

One further point. Colonel Walker says that although htheria was common in Land Oldenburg during the riod of observation, it did not reach epidemic pro- rtions. He says its weekly incidence averaged about per 100,000 of the population. An incidence of at order in Dublin would certainly be regarded as aching epidemic proportions. J. C. GAFFNEY.

School of Pathology, Trinity College, Dublin.

ANKYLOSING SPONDYLITIS AND FLUOROSIS

SIR,—Mr. Eric Lloyd's interesting letter in your last ue draws attention to the possibility of fluorosis play- g a part in the ætiology of ankylosing spondylitis. nce reading Dr. Oliver Lyth's paper (*Lancet*, 1946, i. 3) I have been at pains to find anything to suggest orosis on examination or history-taking of cases of kylosing spondylitis, but I have drawn a complete ank in the 15 cases I have examined since then. The st 60 cases attending this hospital have come from all arts of the United Kingdom; nearly all were town-wellers drinking the same water and breathing the me air as their normal neighbours. I have one patient ith ankylosing spondylitis of thirty years' duration, but e radiological picture is not that of fluorosis. Were ere an association one might expect radiological changes ore frequently in the aged. At the most, fluorosis ould only be one factor at work in these cases, and the eason why one man suffered while all his neighbours ent free would still be lacking. And why the difference n sex incidence? The progress in the development of the ony changes differs largely in the two conditions, and most f the apparent similarities disappear on closer inspection. Nevertheless, association there may possibly be, and Mr. Lloyd has done a service in drawing attention to the fact.

Westminster Hospital, London, S.W.1. F. DUDLEY HART.

CONVALESCENT HOMES

SIR,—The convalescent-home service in this country has developed in a somewhat haphazard way, mainly outside the hospital framework, with the resulting advantage that the main emphasis is laid on the return to normal life rather than the continuation of medical treatment. But it is, perhaps, in consequence of this independence that convalescence does not, even now, receive adequate recognition as an extension of hospital treatment, but is often regarded as a pleasant but unessential extra.

The attitude of the homes themselves is not always helpful. Some, often those belonging to organisations covering large sections of the community, are reluctant to give details of the care they provide, or to allow visitors from hospitals which send them patients. They regulate the admission of patients through a committee of laymen; and they restrict stay to two weeks, irrespective of medical requirements.

The standards in some homes today are still below those laid down by Florence Nightingale in 1863, and the regimen is by no means always adapted to the mental needs of the patient, which, in the convalescent, are often as great as the physical. Use is rarely made of occupational therapy or recreation under expert supervision. Little interest is taken in the possibilities of research. Scientific knowledge about diet is the exception rather than the rule, and the services of a dietitian are rarely sought.

Many homes work in isolation without any yardstick y which to measure their standards, and without means of exchanging ideas. There is need for greater curiosity on the part of homes, but the absence of any reliable pool of information and advice has been a great drawback. Action now being taken by King Edward's Hospital Fund (*Lancet*, April 5, p. 454) to remedy this in the London area needs to be extended over the whole country. In this way standards could be raised and gaps in provision filled; whereas coercion and regimentation might well destroy many of the smaller homes, which, whatever their faults, are a valuable part of the convalescent-home service in Great Britain.

London, S.W.1. MARJORIE L. WARD.

Public Health

Smallpox

FIFTEEN separate introductions of Asiatic smallpox occurred during 1946. Fortunately, on each occasion vaccination and surveillance of contacts brought the disease under control with remarkable speed, and only 40 persons became infected during the year.

In mid-February, after an interval of seven months, the disease again appeared, and since then 33 cases have been notified up to April 15 (15 at Grimsby, 2 at Stepney, 7 at Scunthorpe, 1 at Doncaster, and 8 at Bilston). The disease was introduced from an unknown source into a common lodging-house at Grimsby, where 2 old men sickened on Feb. 13 and 16. Subsequently, 13 further cases arose, all of which were in the direct line of contact with the 2 original cases. 1 was in a man who had spent the night of Feb. 16 at the lodging-house, and subsequently developed smallpox at his home in Grimsby. 2 members of the staff of the Public-health department who had been concerned with the disinfecting of the lodging-house developed smallpox while living at home. With the exception of these 3, all the secondary cases occurred among the contacts either at the common lodging-house (4) or in the ward of the public-assistance infirmary (6) into which the original patient was unfortunately admitted. The total number of cases in this outbreak was thus 15. There were 6 deaths; the high mortality was associated with the advanced age of the patients, and in 4 with previous debilitating disease. The last case at Grimsby was removed on March 9, and the town is now believed to be free from infection.

It is probable that an unidentified contact at Grimsby infected an attendant at a hostel for seamen at Stepney; fortunately, this man was admitted early in the disease to a general hospital, where he infected only 1 patient. Since the removal of this secondary case on March 21 no further case has been notified in the London area.

The disease next appeared at Scunthorpe, 28 miles by road from Grimsby. The first patient resided in a common lodging-house where 2 contacts who had absconded from surveillance at Grimsby were staying. Initially this man was diagnosed as having varicella and he was admitted to an infectious-disease hospital. 6 cases in the second generation have been notified, the first developing the rash on April 4. They include a doctor, vaccinated in infancy only, and an unvaccinated nurse, both of whom were attending the patient; the others were residents at the common lodging-house. 5 contacts (Kenny, McGennity, Finegan, Ancliffe, and Andrews) have absconded from this lodging-house while under surveillance; their whereabouts are unknown and they may be incubating or suffering from smallpox.

There is no further information concerning the source of infection at Doncaster. The disease there, in a schoolmaster (rash March 27, removed March 31), was detected early, and prompt vaccination appears to have prevented further spread. Surveillance of contacts has now ceased.

The above series appears to be Asiatic smallpox of moderate severity. In contrast, the disease at Bilston, Staffordshire, is said to be variola minor although it originated in India or Cairo, more probably the former. The third generation of cases (onsets April 3–9, rashes April 5–10) numbers 5, of whom 1, a woman, aged 79, died during the prodromal period. The initial case and the second generation (2), although confidently diagnosed as chickenpox until variola virus was isolated in the laboratory, remained confined to their beds from onset; and the infection is believed to be limited to a circle of relatives and friends in three households. The clinical picture has been misleading. In 2 of the patients there were less than half-a-dozen lesions, and the illness is described as being like "influenza with a few spots."

A further patient is under observation, awaiting diagnosis (April 15), at Rubery, Birmingham.

Because of the difficulties in diagnosis, and, more important, because ambulant cases of variola minor, which are sometimes relatively numerous, if missed, may bring about a wide dispersal of infection, the reappearance of mild smallpox should be viewed with apprehension, and every effort made to detect new foci promptly. A medical officer of health should be consulted whenever there is the slightest suspicion.

From Paris it is reported that there were 32 cases, with 2 deaths, between Feb. 10 and April 2. There have lately been several cases in New York.

Control of Ice-cream

Regulations announced by the Minister of Health for the heat-treatment of ice-cream [1] are similar to those drafted last year.[2] Where a "complete cold mix" is reconstituted with drinking-water and nothing is added other than colouring or flavouring materials, the mixture must be converted into ice-cream within an hour of reconstitution. When any other ingredients are used the mixture must not be kept for more than an hour at a temperature exceeding 45° F before being heated to a temperature of not less than 150° F for 30 minutes or 160° F for 10 minutes; and within 1½ hours it must be cooled to a temperature not exceeding 45° F, and kept below that limit, until freezing is begun. Records from recording thermometers, where these are in use, must be preserved for at least a month. Ice-cream is not to be sold unless it has been kept at a temperature not exceeding 28° F since freezing; or if it has exceeded that temperature it must be submitted to heat treatment again. It must be protected from dirt, dust, or other contamination; and utensils must be thoroughly cleansed immediately after use, and must be kept clean.

These regulations, which are to be enforced by local authorities, become effective on May 1. From a day to be appointed by the Minister, such indicating and recording thermometers as may be required by the local authority must be used during processing and storage; the imposition of this regulation is being deferred to allow time for the purchase of thermometers. In view of the possible difficulty in obtaining equipment, proof of having ordered the necessary apparatus shall constitute a defence against charges of infringement of the cooling regulation up to May 1, 1948, provided every attempt has been made to comply as far as possible with the regulation.

The Minister has decided against imposing a bacteriological standard of cleanliness; but he commends the methylene-blue test,[3] and suggests that further investigation is needed if samples consistently fail to reach grade 1 or 2.

Report on Nutrition

In the latest Ministry of Health survey of nutrition,[4] covering the period from last October to January, 4658 people were examined. The proportion with nutrition classified as good was 92·9%, while the proportion classified as fair was 6·6%, and as poor 0·5%. These figures differ little from those at the previous survey for January–June, 1946; but the percentage rated as good is 3·2 higher than in the 24,723 people examined between June, 1942, and June, 1946. Comparison is, however, difficult, since the earlier surveys were carried out by selection in formerly depressed areas, when improvements in the national dietary from the more equitable distribution of food had been operating only a short time.

In the latest survey the incidence of folliculosis was 8·5%, compared with 15·6% for the whole of last year; while that of gingivitis was 14·7%, compared with 8·8%. Among school-children the percentage classified as nutritionally good was 90·9, compared with 92·9.

Infectious Disease in England and Wales

WEEK ENDED APRIL 5

Notifications.—Smallpox, 2; scarlet fever, 995; whooping cough, 1775; diphtheria, 184; paratyphoid, 6; typhoid, 8; measles (excluding rubella), 8843; pneumonia (primary or influenzal), 730; cerebrospinal fever, 86; poliomyelitis, 4; polioencephalitis, 1; encephalitis lethargica, 1; dysentery, 44; puerperal pyrexia, 115; ophthalmia neonatorum, 68. No c cholera, plague, or typhus was notified during the

The 2 cases of smallpox were notified at Scunthorpe and Do respectively.

Deaths.—In 126 great towns there were 1 (0) from enteric fever, 1 (0) from scarlet fever, 5 (0) diphtheria, 20 (0) from measles, 13 (2) from wh cough, 89 (20) from diarrhœa and enteritis under years, and 27 (6) from influenza. The figures in theses are those for London itself.

The number of stillbirths notified during the was 285 (corresponding to a rate of 32 per the total births), including 27 in London.

Appointments

ACFIELD, J. R., M.B. Leeds, D.O.M.S.: asst. ophthalmic Hull Royal Infirmary.

BARKER, H. A., M.B. Edin., D.P.H.: senior M.O., health de and deputy medical superintendent, Bradford M General Hospital.

BIRKETT, A. N., F.R.C.S.: asst. orthopædic surgeon, Not General Hospital.

COWAN, EMANUEL, M.B. Dubl.: asst. maternity and child officer and asst. M.O.H., Portsmouth City.

*GIBB, ERIC, D.M. Oxfd, M.R.C.P.: asst. physician, St. Barthol[illegible] *Hospital, London.*

HOLLINGSWORTH, GEOFFREY, M.B. Edin., D.OBST.R.C.O.G., D.M.R.: consultant radiodiagnostician, Northampton General Ho[illegible]

JONES, C. D. F., M.B.E., M.B. Lond., F.R.C.S.: asst. surgeon, [illegible] Sheffield Infirmary and Hospital.

KENDALL, DAVID, D.M. Oxfd, M.R.C.P.: neurologist, West K[illegible] General Hospital, Maidstone, and Kent County Ophth[illegible] and Aural Hospital, Maidstone.

MENZIES, ALEXANDER, M.B. Edin., D.P.H.: deputy M.O.H., deputy school M.O., and deputy port M.O., Middlesbrough.

PEAKER, MARGARET, M.R.C.S.: asst. school M.O., Middlesbrough.

SUMMERS, T. C., M.B. Lond., F.R.C.S.: ophthalmic surgeon, Kin[illegible] George Hospital, Ilford.

SWEENEY, P. J., M.B. N.U.I., M.R.C.P., M.R.C.P.I.: first asst., medical department, Royal Victoria and West Hants Hospital, Bournemouth.

Radcliffe Infirmary, Oxford:

PERCIVAL, R. H., B.M. Oxfd, F.R.C.S.: surgical registrar.
SHEPHERD, J. A., M.D. St. And., F.R.C.S.E.: surgical tutor.
SMITH, F., F.R.C.S.: surgical registrar.

Royal Albert Edward Infirmary and Dispensary, Wigan:

Visiting physicians:
GOLDMAN, H. P., M.B. Glasg., M.R.C.P.
SUTTON, W. S., M.B. Lpool, M.R.C.P. (temporary appointment).

Examining Factory Surgeons:

ARMSTRONG, REGINALD, O.B.E., M.B. Durh.: Rothbury, Northumberland.
CAMERON, D. F., M.B. Leeds: Builth, Brecon.
FENN, C. M., M.B. Birm.: Llanwrtyd Wells, Brecon.
MORRISON, E. F. S., M.C., M.B. Dubl.: Kibworth, Leics.

* Amended notice

Births, Marriages, and Deaths

BIRTHS

CRITIEN.—On March 30, in Malta, the wife of Surgeon Lieut.-Commander G. R. Critien, R.N.—a daughter.

MCAULIFFE-CURTIN.—On March 25, in Dublin, Dr. Maeve Kennedy, wife of Mr. J. M. McAuliffe-Curtin, F.R.C.S.I.—a daughter.

MASON.—On April 9, the wife of Dr. A. S. Mason—a son.

MAWSON.—On April 8, the wife of Dr. Richard Mawson—a son

MOWLL.—On April 5, at Surbiton, the wife of Dr. R. F. Mowll—a daughter.

MURRAY.—On April 8, in London, the wife of Dr. R. Murray—a daughter.

WISE.—On April 7, at Sandwich, Kent, the wife of Dr. C. S. Wise—a daughter.

MARRIAGES

DEWAR—THOMSON.—On April 10, at Newcastle-on-Tyne, Hewan Archdale Dewar, M.D., to Margaret Thomson.

NEVIN—LEESON.—On April 8, at Winchester, Robert Wallace Nevin, F.R.C.S., to Audrey Leeson.

ROBINSON—NIMMO.—On April 5, at Adel, Yorks, Cecil H. V. Robinson to Charlotte S. Nimmo, captain R.A.M.C.

ROSS—HOARE.—On April 11, at Epsom, J. N. MacBean Ross, M.D., to Betty Adine Hoare.

DEATHS

BANTING.—On April 8, at Ramsgate, Cecil Banting, M.D. Lond., F.R.C.S.

BOWLE.—On April 4, at Bexhill, Charles William Bowle, M.B. Camb., lieut.-colonel R.A.M.C., retd., aged 67.

CARSON.—On April 12, at Richmond, Surrey, Walter Peter Carson, M.B. Dubl., lieut.-colonel I.M.S., retd., aged 91.

COPEMAN.—On April 11, at Hove, Sydney Monckton Copeman, M.D. Camb., F.R.C.P., F.R.S., aged 85.

GODWIN.—On April 8, Herbert James Godwin, O.B.E., M.B. Durh., F.R.C.S.E., of Liss, Hants.

LITTLEJOHNS.—On April 6, at Farnham, Surrey, Archibald Smith Littlejohns, M.R.C.S., D.S.O., lieut.-colonel late R.A.M.C.

MITCHELL.—On April 4, at Bridge of Allan, John Stevenson Mitchell, M.B. Edin., F.R.C.S.E.

Notes and News

HONOURING A GREAT FRENCHMAN

At the opening of the Pasteur exhibition in London on April 9, M. René Varin, cultural counsellor at the French Embassy, pointed to the spontaneous nature of Louis Pasteur's work; rather than pursue a predetermined plan he investigated, with an open mind, such subjects as were brought to him. Sir Henry Dale, O.M., emphasised the close friendship between Pasteur and his British contemporaries, and the ubiquity of his work.

The exhibition, lent by the Palais de la Découverte, Paris, will remain open at the Science Museum, South Kensington, until May 26. Such homage to the great, if it is to grip the public's attention, must catch something of its subject's personality or of the purpose and the drama of his life. With the arts it is easy; the painter lives again in the gallery and the musician at the festival. With science it is not so easy; for here the achievement is not readily sensible to the eye or ear. This exhibition shows the difficulty very clearly. The story of Pasteur's life and work is told on a series of coloured boards inscribed with variously coloured inks. The tale could be read just as well, and certainly more comfortably, from the printed page. The necessary "lift," to persuade the casual visitor to follow the story to its end, would be provided by sufficient illustrations; and these, unfortunately, are lacking. Contemporaneous photographs are not to be expected; but Pasteur lives on in his influence on our daily lives; and pictures suggesting our debt to him, even today, would have brought home, like nothing else, the measure of his greatness. The exhibition is, however, enlivened by a display of letters in his hand and by some of the apparatus he used. If only for this section, it should be visited by those not too preoccupied with the present to glance back at the great past.

University of Oxford

The George Herbert Hunt travelling scholarship for 1947 has been awarded to Mr. Selwyn Taylor, M.CH., of Keble College.

University of Durham

On Thursday, May 29, at 5.15 P.M., at the Royal Victoria Infirmary, Newcastle-on-Tyne, Prof. G. Grey Turner will deliver the first Rutherford Morison lecture. He has chosen as his subject Rutherford Morison and his Achievement in Surgery.

Royal College of Physicians of London

On Tuesday and Thursday, May 20 and 22, Prof. R. E. Lane will deliver the Milroy lectures at the college, Pall Mall East, S.W.1, at 5 P.M. He will speak on the Care of the Lead Worker.

Society of Apothecaries of London

The honorary freedom of the society is to be conferred on Sir Stanley Hewett, and the mastery of midwifery, honoris causa, on Sir Allen Daley, Sir Eardley Holland, and Sir William Fletcher Shaw. The society's gold medal in therapeutics for 1947 has been awarded to F. H. S. Curd, D. G. Davey, and F. L. Rose, in recognition of their combined research which culminated in the discovery of 'Paludrine.'

British Legion Rheumatology Unit

At a meeting with the Minister of Health on April 14 a deputation from the British Legion suggested that experience gained in the British Legion unit of rheumatology, which was set up last June at the Three Counties Emergency Hospital, Arlesey, Beds., showed that the rheumatic and arthritic diseases could be treated successfully. At the centre, to which Dr. C. B. Heald is consultant, no new treatment was given, but various known methods were intensively applied, and the greater proportion of patients had left the unit to return to work. The deputation therefore suggested that similar units should be set up in all hospital regions. The Minister replied that he had watched this experiment with great interest and he valued highly the constructive nature of the work done by the Legion, which had resulted in so many men returning to their normal employment. The British Legion unit, complete with staff, was to be transferred to the Royal Free Hospital, and he fully intended to encourage the provision of further units on a similar basis.

Royal College of Surgeons of England

At a meeting of the council, held on April 10, with Sir Alfred Webb-Johnson, the president, in the chair, Dr. S. S. Beare (Weybridge) and Dr. E. H. R. Altounyan (Aleppo) were elected as fellows of the college, being members of over 20 years' standing. The Begley prize was awarded to Mr. R. C. Jordan, of Cardiff.

Prof. W. E. Gye, F.R.S., and Dr. James Craigie, F.R.S., were appointed Imperial Cancer Research Fund lecturers for 1947. Mr. E. A. Crook was re-elected a member of the court of examiners. It was decided to hold an additional primary examination for the fellowship in July, 1947. The subject set for the Jacksonian prize for 1948 was Malignant Disease of the Thyroid Gland.

The category of those entitled to attend the monthly dinners was widened so as to include fellows (when elected) and licentiates in dental surgery, holders of any of the specialist postgraduate diplomas, and all postgraduate students of the college, together with their wives and guests.

The following posts were recognised for the final fellowship examination:

House-surgeon and resident officer, Demerdash Hospital, Egypt; assistant medical officer, Paddington Hospital; senior house-surgeon and supernumerary house-surgeon, Royal Buckinghamshire Hospital, Aylesbury.

A diploma of fellowship was granted to P. D. Trevor-Roper, and the following diplomas were granted, jointly with the Royal College of Physicians:

D.T.M. & H.—H. E. Al-Abed, Harry Annamunthodo, D. W. Bell, R. H. Bell, J. S. Calnan, M. V. Chari, F. G. Domaingue, A. E. Eissa, H. S. Fuller, V. V. Gharpure, D. J. Gilbert, John Harper, Leslie Jacobson, V. N. Jai, Sze-Kin Kaan, Endre Kertész, R. R. Lam, J. I. Lesh, K. H. Lim, J. P. P. Mackey, R. D. Maclean, R. C. Macleod, G. Y. Nan, M. G. Nelson, Y. H. Ng, Qaiyum Pasha, S. H. Patel, I. B. Patwari, Abdurrahman Qattan, R. V. Rele, S. C. Sanghani, A. O. Sasegbon, K. S. Seal, I. H. Syed, W. J. U Tin, J. M. Vaizey, A. J. N. Warrack, Dorothy W. Wells, J. P. F. Whelan.

D.C.H.—Esmé Abelheim, J. M. Alexander, Raymond Asquith, J. N. Berry, B. W. Beynon, D. M. Brierley, Margaret Brodigan, Janos Brody, J. C. Brown, R. W. W. Brown, Janet Cameron, W. A. B. Campbell, F. S. Carter, R. H. Caughey, Roma N. Chamberlain, N. A. Daniel, H. H. Davies, H. L. Ellis, Edith M. Evans, C. G. Fagg, D. M. Foubister, Elsie C. Gibbons, Mildred C. Green, Joan Guy, Homer Habibis, Nell Hamlin, Margaret A. Hay, Frances A. Hepburn, J. B. Heycock, Patricia E. Hingle, Aron Holzel, J. N. Horne, Margaret E. Hughes, Joseph Jacobs, A. P. Kalra, Nora Kelly, Doreen M. King, Philip Kushlick, J. H. Lawrence, Joan M. Levett, M. E. MacGregor, Runa B. Mackay, G. F. Maggioni, S. L. Malhotra, N. M. Mann, Betty M. Margetts, Paul Maurice, Lilian Morris, P. D. Moss, E. F. Murphy, A. P. Norman, W. H. Opie, Arnold Palley, A. N. Pearson, V. R. Pickles, B. W. Powell, P. M. M. Pritchard, E. P. Quibell, Joan M. Redshaw, Attracta G. Rewcastle, Frank Rousseau, G. R. Royston, Alexander Russell, Isabel S. Smellie, Marion E. Smith, Angele M. P. Snow, Margaret H. Stanfield, J. H. Steeds, Eluned M. Steven, J. K. Steward, Marian E. Sturrock, Laura Thompson, J. P. M. Tizard, I. P. Todd, A. B. Tompkins, V. V. Tracey, G. B. R. Walkey, Pauline H. Webb, R. C. Webster, R. H. White-Jones, Llary M. Williams, D. A. J. Williamson.

London Association for Hospital Services Limited

This association, which was introduced five years ago by King Edward's Hospital Fund under the chairmanship of Sir Bernard Docker and Dr. W. Russell Brain to enable provision to be made for the cost of serious illness, is now offering the following increased benefits: an additional £1 1*s.* per week; cover for tonsillectomy, previously excluded; and a choice of three, instead of two, rates of subscription. Further particulars of the scheme, which was lately described in our columns (March 15, p. 352), may be had from the secretary of the association, 10, Old Jewry, E.C.2.

Travelling Fellowships in Medicine

The Medical Research Council invite applications for the following travelling fellowships for 1947–48.

Rockefeller Medical Fellowships.—These fellowships are intended for graduates resident in this country who have had some training in research work in clinical medicine or surgery, or in some other branch of medical science, and who are likely to profit by a period of work at a centre in the United States or elsewhere abroad, before taking up positions for higher teaching or research in the United Kingdom.

Dorothy Temple Cross Research Fellowships in Tuberculosis.—The object of these fellowships is to give opportunities for study or research to British subjects of either sex "intending to devote themselves to the advancement by teaching or research of curative or preventive treatment of tuberculosis in all or any of its forms." They will, as a rule, be awarded to candidates who wish to make their studies or inquiries elsewhere than in the United Kingdom. They will ordinarily be awarded for one academic year.

The fellowships carry a stipend of £525 per annum for a single fellow and £800 for a married fellow, together with allowances for travelling and incidental expenses. Applications must be lodged, not later than June 1, with the secretary of the council, 38, Old Queen Street, Westminster, S.W.1, from whom further particulars may be had.

and every effort made to detect new foci promptly. A medical officer of health should be consulted whenever there is the slightest suspicion.

From Paris it is reported that there were 32 cases, with 2 deaths, between Feb. 10 and April 2. There have lately been several cases in New York.

Control of Ice-cream

Regulations announced by the Minister of Health for the heat-treatment of ice-cream[1] are similar to those drafted last year.[2] Where a "complete cold mix" is reconstituted with drinking-water and nothing is added other than colouring or flavouring materials, the mixture must be converted into ice-cream within an hour of reconstitution. When any other ingredients are used the mixture must not be kept for more than an hour at a temperature exceeding 45° F before being heated to a temperature of not less than 150° F for 30 minutes or 160° F for 10 minutes; and within 1½ hours it must be cooled to a temperature not exceeding 45° F, and kept below that limit, until freezing is begun. Records from recording thermometers, where these are in use, must be preserved for at least a month. Ice-cream is not to be sold unless it has been kept at a temperature not exceeding 28° F since freezing; or if it has exceeded that temperature it must be submitted to heat treatment again. It must be protected from dirt, dust, or other contamination; and utensils must be thoroughly cleansed immediately after use, and must be kept clean.

These regulations, which are to be enforced by local authorities, become effective on May 1. From a day to be appointed by the Minister, such indicating and recording thermometers as may be required by the local authority must be used during processing and storage; the imposition of this regulation is being deferred to allow time for the purchase of thermometers. In view of the possible difficulty in obtaining equipment, proof of having ordered the necessary apparatus shall constitute a defence against charges of infringement of the cooling regulation up to May 1, 1948, provided every attempt has been made to comply as far as possible with the regulation.

The Minister has decided against imposing a bacteriological standard of cleanliness; but he commends the methylene-blue test,[3] and suggests that further investigation is needed if samples consistently fail to reach grade 1 or 2.

Report on Nutrition

In the latest Ministry of Health survey of nutrition,[4] covering the period from last October to January, 4658 people were examined. The proportion with nutrition classified as good was 92·9%, while the proportion classified as fair was 6·6%, and as poor 0·5%. These figures differ little from those at the previous survey for January–June, 1946; but the percentage rated as good is 3·2 higher than in the 24,723 people examined between June, 1942, and June, 1946. Comparison is, however, difficult, since the earlier surveys were carried out by selection in formerly depressed areas, when improvements in the national dietary from the more equitable distribution of food had been operating only a short time.

In the latest survey the incidence of folliculosis was 8·5%, compared with 15·6% for the whole of last year; while that of gingivitis was 14·7%, compared with 8·8%. Among school-children the percentage classified as nutritionally good was 90·9, compared with 92·9.

Infectious Disease in England and Wales

WEEK ENDED APRIL 5

Notifications.—Smallpox, 2; scarlet fever, 995; whooping cough, 1775; diphtheria, 184; paratyphoid, 6; typhoid, 8; measles (excluding rubella), 8343; pneumonia (primary or influenzal), 730; cerebrospinal fever, 86; poliomyelitis, 4; polioencephalitis, 1; encephalitis lethargica, 1; dysentery, 44; puerperal pyrexia, 115; ophthalmia neonatorum, 68. No cholera, plague, or typhus was notified during the

The 2 cases of smallpox were notified at Scunthorpe and respectively.

Deaths.—In 126 great towns there were 1 (0) from enteric fever, 1 (0) from scarlet fever, 5 (0) diphtheria, 20 (0) from measles, 13 (2) from wh cough, 89 (20) from diarrhœa and enteritis under years, and 27 (6) from influenza. The figures in theses are those for London itself.

The number of stillbirths notified during the was 285 (corresponding to a rate of 32 per the total births), including 27 in London.

Appointments

ACFIELD, J. R., M.B. Leeds, D.O.M.S.: asst. ophthalmic Hull Royal Infirmary.

BARKER, H. A., M.B. Edin., D.P.H.: senior M.O., health de and deputy medical superintendent, Bradford M General Hospital.

BIRKETT, A. N., F.R.C.S.: asst. orthopædic surgeon, No General Hospital.

COWAN, EMANUEL, M.B. Dubl.: asst. maternity and child officer and asst. M.O.H., Portsmouth City.

*GIBB, ERIC, D.M. Oxfd, M.R.C.P.: asst. physician, St. Barth Hospital, London.

HOLLINGSWORTH, GEOFFREY, M.B. Edin., D.OBST.R.C.O.G., consultant radiodiagnostician, Northampton General H

JONES, C. D. F., M.B.E., M.B. Lond., F.R.C.S.: asst. surgeon, Sheffield Infirmary and Hospital.

KENDALL, DAVID, D.M. Oxfd, M.R.C.P.: neurologist, West General Hospital, Maidstone, and Kent County Oph and Aural Hospital, Maidstone.

MENZIES, ALEXANDER, M.B. Edin., D.P.H.: deputy M.O.H., school M.O., and deputy port M.O., Middlesbrough.

PEAKER, MARGARET, M.R.C.S.: asst. school M.O., Middlesbrough.

SUMMERS, T. C., M.B. Lond., F.R.C.S.: ophthalmic surgeon, George Hospital, Ilford.

SWEENEY, P. J., M.B. N.U.I., M.R.C.P., M.R.C.P.I.: first asst., department, Royal Victoria and West Hants H Bournemouth.

Radcliffe Infirmary, Oxford:

PERCIVAL, R. H., B.M. Oxfd, F.R.C.S.: surgical registrar.

SHEPHERD, J. A., M.D. St. And., F.R.C.S.E.: surgical tutor

SMITH, F., F.R.C.S.: surgical registrar.

Royal Albert Edward Infirmary and Dispensary, Wigan:

Visiting physicians:

GOLDMAN, H. P., M.B. Glasg., M.R.C.P.

SUTTON, W. S., M.B. Lpool, M.R.C.P. (temporary appointment).

Examining Factory Surgeons:

ARMSTRONG, REGINALD, O.B.E., M.B. Durh.: Rothbury, Northumberland.

CAMERON, D. F., M.B. Leeds: Builth, Brecon.

FENN, C. M., M.B. Birm.: Llanwrtyd Wells, Brecon.

MORRISON, E. F. S., M.C., M.B. Dubl.: Kibworth, Leics

* Amended notice

Births, Marriages, and Deaths

BIRTHS

CRITIEN.—On March 30, in Malta, the wife of Surgeon Lieut.-Commander G. R. Critien, R.N.—a daughter.

MCAULIFFE-CURTIN.—On March 25, in Dublin, Dr. Maeve Kennedy, wife of Mr. J. M. McAuliffe-Curtin, F.R.C.S.I.—a daughter.

MASON.—On April 9, the wife of Dr. A. S. Mason—a son.

MAWSON.—On April 8, the wife of Dr. Richard Mawson—a son.

MOWLL.—On April 5, at Surbiton, the wife of Dr. R. F. Mowll—a daughter.

MURRAY.—On April 8, in London, the wife of Dr. R. Murray—a daughter.

WISE.—On April 7, at Sandwich, Kent, the wife of Dr. C. S. Wise—a daughter.

MARRIAGES

DEWAR—THOMSON.—On April 10, at Newcastle-on-Tyne, Hewan Archdale Dewar, M.D., to Margaret Thomson.

NEVIN—LEESON.—On April 8, at Winchester, Robert Wallace Nevin, F.R.C.S., to Audrey Leeson.

ROBINSON—NIMMO.—On April 5, at Adel, Yorks, Cecil H. F. Robinson to Charlotte S. Nimmo, captain R.A.M.C.

ROSS—HOARE.—On April 11, at Epsom, J. N. MacBean Ross, M.D., to Betty Adine Hoare.

DEATHS

BANTING.—On April 8, at Ramsgate, Cecil Banting, M.D. Lond., F.R.C.S.

BOWLE.—On April 4, at Bexhill, Charles William Bowle, M.B. Camb., lieut.-colonel R.A.M.C., retd., aged 67.

CARSON.—On April 12, at Richmond, Surrey, Walter Peter Carson, M.B. Dubl., lieut.-colonel I.M.S., retd., aged 91.

COPEMAN.—On April 11, at Hove, Sydney Monckton Copeman, M.D. Camb., F.R.C.P., F.R.S., aged 85.

GODWIN.—On April 8, Herbert James Godwin, O.B.E., M.B. Durh., F.R.C.S.E., of Liss, Hants.

LITTLEJOHNS.—On April 6, at Farnham, Surrey, Archibald Smith Littlejohns, M.R.C.S., D.S.O., lieut.-colonel late R.A.M.C.

MITCHELL.—On April 4, at Bridge of Allan, John Stevenson Mitchell, M.B. Edin., F.R.C.S.E.

SURGICAL HANDICRAFT*

Sir Heneage Ogilvie
K.B.E., D.M., M Ch. Oxfd, F.R.C.S.
URGEON TO GUY'S HOSPITAL; CONSULTING SURGEON TO THE ROYAL BUCKS HOSPITAL, AYLESBURY

Surgery began as a handicraft. In ancient times it was conducted by journeymen who plied their simple rade, often coupled with that of the barber, at fairs and inns. Gradually, through the vision and by the abours of a series of guilds and corporations to which his College stands in direct succession, it was elevated from a humble craft to a science and art. Within the last few years British surgery has attained a level higher than it has ever reached before; we have hitched our wagon to a star; let us see that the wheels are well planted on the road.

I speak of the craft of surgery, for the word craft retains unsullied its honourable tradition of sound work well done, whereas the word "art" is dragged down under the weight of those who claim its appellation. The hairdresser, the crooner, the juggler, the Hollywood extra, are all artists, whereas the watchmaker, the plumber, the smith, the carpenter, and the shipwright are proud to remain craftsmen. A surgeon, like a shipwright, must consider the design and purpose of the task he is about to undertake, his materials, his tools, the arrangement of his workshop, and the training of his assistants. His aim is the same, to please the customer.

The tasks we undertake in surgery are five:

(1) We incise; to gain access to all deep regions, to drain abscesses, to remove stones, and to provide an outlet to the surface.
(2) We excise tumours and dead or unhealthy tissue.
(3) We repair damage; we stop hæmorrhage, close perforations, approximate fractures, suture tears, and close the incisions we ourselves have made.
(4) We remodel, to restore form on the surface of the body, or function in its deeper structures.
(5) We transplant, to substitute what we may for that which has been lost.

The tissues that are the material of our craft are for the most part skin, fat, connective tissue, muscle, and bone.

SKIN

Skin is the ensheathing coat, the doorway to the rest of the body. A wound is not healed till the skin is healed, nor is its sterility secure till the skin-cover is complete. Skin consists of a tough felting of connective tissue with an epithelial cover. It possesses a considerable amount of elasticity, but this elasticity varies from place to place, according to the functional needs of the part.

The elasticity of the skin is a necessary quality in the external envelope of a body that grows, moves, and constantly alters the position and contour of its component parts. A cut in the skin tends to gape. An excised Wolff graft is smaller, and the hole left behind is larger, than the pattern originally marked on the surface (fig. 1). The elasticity varies from place to place according to the functional needs of the part. Over the abdomen it is well marked, to allow room for the constantly recurring expansion of respiratory movement, the frequent distension of meals, and the occasional encroachment of babies; over the back it need not, and therefore does not, stretch to any great extent. The elasticity is graded not merely to the extent but also to the direction of the stresses. Over parts that move, the skin must be able to stretch during extension and take up the slack during flexion, to twist during rotation, and always to return to the position of rest, which for any part of the body is usually that assumed in sleep.

But elasticity alone could not adapt the skin to the flexure surface of a hinge joint, where the tendency to shorten would make it bridge the angle during flexion and come away from the surface. This tendency is counteracted by the flexure creases which appear in the skin at all joints (fig. 2). As Wood Jones has pointed out, these creases are planes of stasis where the skin is anchored by a web of fibrous tissue that extends through the fatty layer to the deep fascia.

Incisions.—The first step in any surgical operation is an incision through the skin; and the last step is suture of the skin so that the least possible trace of the operation in altered function or visible scar remains. The patient will judge the success of the operation by the appearance of the scar rather than by what has been done beneath it.

An incision must give access for the operation that is to be performed; but, in planning it, the functions and movements of the skin in that part and the need to suture it exactly as it lay before must be borne in mind. In general, incisions should be made across lines of tension, particularly over the flexures of joints, where the movement, the elasticity to accommodate it, and therefore inherent tension are always greatest—i.e., in places like the front of the neck and the lower half of the abdominal wall (fig. 3). By cutting across lines of tension the elasticity of the skin in that line is interfered with only by the width of the inextensile scar, which with first-intention healing is measured in fractions of a millimetre rather than by its length, which always extends in inches. What is functionally desirable may not always be anatomically possible. Transverse incisions over Scarpa's triangle are excellent for any approach to the vessels, but of little value as an approach to the underlying hip-joint. Transverse incisions over the distal joints of the limbs are limited in length by the need to avoid the sensory nerves and surface veins that run longitudinally, and are suitable for small and superficial operations only. Where possible an incision should be made in a natural crease, for only where a surgical scar corresponds to a physiological one can it achieve perfection—perfect invisibility and function perfectly restored.

Royal Flemish Academy of Medicine of Belgium

Prof. E. D. Adrian, F.R.S., Sir Henry Dale, F.R.S., Mr. W. Sampson Handley and Prof. A. V. Hill, D.SC., F.R.S., have been elected foreign members of the academy.

Lund Research Fellowships in Diabetes

To encourage research in diabetes the Diabetic Association is offering whole or part time fellowships which will carry an annual salary of up to £750. A medical and scientific subcommittee will administer the fund and further particulars will be found in our advertisement columns.

St. Bartholomew's Hospital, London

The medical college is shortly to appoint a man or woman "to give practical instruction to medical students in the proper use of the social services available for children." The appointment is to be whole time and will carry a salary of not less than £450.

Irish Tuberculosis Society

A meeting of the society will be held at the Royal College of Surgeons, Dublin, on Friday, May 2, at 7.30 P.M., when Dr. G. S. Todd will speak on Collapse Therapy; Dr. William MacPhail on Rehabilitation; Dr. Morgan Crowe on Dispensary Organisation; and Mr. F. J. Henry on Surgery in the Treatment of Pulmonary Tuberculosis.

Conference on Industrial Health

The north-west area group of the Association of Scientific Workers are holding a conference on Saturday, April 26, at 2.45 P.M., at Milton Hall, Deansgate, Manchester, at which workers, management, and medical staff will discuss health problems in industry. Dr. C. Metcalfe Brown will be in the chair, and the speakers will include Prof. R. E. Lane and Dr. M. W. Goldblatt. Further information may be had from Mr. H. G. Bevan, 79, Russell Road, Manchester, 16.

Tribute to Sir Leonard Parsons

On March 28 a service of dedication was held at the Children's Hospital, Birmingham, when the babies' block was named the "Leonard Parsons block," to commemorate his services to sick children. Later at a private dinner held in his honour, Sir Leonard was presented with his portrait and an illuminated address recording the thanks of the board of management for his services to the hospital as physician and research-worker. Sir Leonard and Lady Parsons were also given a silver tea-service.

Production and Care of Laboratory Animals

On Monday, April 21, and May 12 the biological methods group of the Society of Public Analysts will hold the concluding meetings of their symposium on this subject, which opened on March 17. The meetings will take place at 6 P.M., at 1, Wimpole Street, London, W.1, and on April 21 Dr. H. J. Parish will speak on Common Diseases and Mr. N. T. Gridgeman on Records. On May 12 Dr. J. I. M. Jones and Mr. Eric Wood, PH.D., will read a paper on Housing, and afterwards there will be a general discussion of all the subjects covered at the three meetings.

Kent Pædiatric Society

The first general meeting of this society will be held on Saturday, April 26, at 2 P.M., at the County Hospital, Farnborough, Kent, when Dr. Duncan Leys will speak on a County Pædiatric Service. The society has been formed to encourage the study of children in health and in disease, to promote the welfare of children in the county, and to afford opportunity for coöperation between members of the child-health services. Membership is open to doctors engaged wholly or partly in work among children, including general practitioners, whether resident in the county or not. The secretary is Dr. P. N. Swift, pædiatric unit, Farnborough Hospital, Kent.

British Medical Association

At a meeting of the council of the association held on April 2 a unanimous recommendation was made to the representative body that Sir Hugh Lett be re-elected president for 1947–48. The annual meeting of the association in 1948 will be held at Cambridge and Sir Lionel Whitby was recommended as president for 1948–49.

Dr. Guy Dain, chairman of the council, Dr. Charles Hill, secretary of the association, Dr. Hugh Clegg, editor of the *British Medical Journal*, and Dr. J. A. Pridham, chairman of the international relations committee, are to represent the association at the centenary celebrations of the American Medical Association to be held at Atlantic City in June of this year.

Institute of Metals

On Thursday, April 24, at 7 P.M., at the James Memorial Institute, Great Charles Street, B Dr. Neil G. Marr will address the Birmingham section of institute on *Medical Services in the Non-ferrous Industry.*

Change of Owner

The Minister of Health has asked all voluntary non- hospitals to return to him by June 30 a statement of assets as at Dec. 31, 1946, so that a central record may be prepared to facilitate the transfer of hospital property under the National Health Service Act. Hospitals are asked to state any conditions attaching to their endowments so that due consideration may be given to them.

A new quarterly, the *British Journal of Nutrition*, is to be published for the Nutrition Society by Cambridge University Press. It will include, as well as original work, the society's *Proceedings*, which at present appear separately. Papers for publication should be sent to the chairman of the editorial board, Mr. S. K. Kon, D.SC., at the National Institute for Research in Dairying, Shinfield, Reading. Subscriptions (for non-members of the society £3 per volume of four quarterly parts, or £1 for each separate part) should be addressed to the Cambridge University Press, 200, Euston Road, London, N.W.1.

Corrigendum.—Sir Adolphe Abrahams writes to point out that the diagrammatic representation of irregularity of living in his article on Chronic Fatigue (*Lancet*, 1945, ii, 421) was wrongly attributed to Richard Cabot. The figure was inspired by the frontispiece of Cabot's book *What Men Live By*, but was the work of Dr. E. J. Kepler (*Proc. Mayo Clin.* 1942, **17**, 340).

Diary of the Week

APRIL 20 TO 26

Monday, 21st

ROYAL COLLEGE OF SURGEONS, Lincoln's Inn Fields, London W.C.
5 P.M. Mr. Rainsford Mowlem: Replacement of Skin Loss in Traumatic Injuries.
6.15 P.M. Prof. R. R. Macintosh: Anæsthesia in Abdominal Surgery.

Tuesday, 22nd

ROYAL COLLEGE OF SURGEONS
6.15 P.M. Dr. Geoffrey Organe: Anæsthesia in Thoracic Surgery.
ROYAL SOCIETY OF MEDICINE, 1, Wimpole Street, W.1
8 P.M. *Medicine.* Dr. Geoffrey Evans, Mr. A. Dickson Wright, Dr. C. Wyndham: Management of Patients with Essenti Hypertension.
UNIVERSITY OF EDINBURGH
5 P.M. (University New Buildings.) Dr. C. H. Kellaway, F.R.S. Perfusion Experiment in the Study of Tissue Injur (Sharpey-Schafer lecture.)

Wednesday, 23rd

ROYAL COLLEGE OF SURGEONS
5 P.M. Mr. Julian Taylor: Surgery of the Anterior Cran Fossa.
6.15 P.M. Dr. Bernard Johnson: Intravenous Anæsthesia

Thursday, 24th

ROYAL COLLEGE OF SURGEONS
5 P.M. Sir Lionel Whitby: Blood Transfusion.
6.15 P.M. Dr. Stanley Rowbotham: Anæsthesia in Thyro Surgery.
ROYAL SOCIETY OF MEDICINE
8 P.M. *Urology.* Mr. H. Hamilton Stewart: Treatment Hydronephrosis associated with Abnormal Vessels.
MEDICO-LEGAL SOCIETY
8.15 P.M. (26, Portland Place, London, W.1.) Mr. David Mac PH.D.: Marriage Breakdown and Divorce.

Friday, 25th

ROYAL COLLEGE OF SURGEONS
6.15 P.M. Dr. W. S. McConnell: Anæsthesia in Thyroid Surger
UNIVERSITY COLLEGE, London, W.C.1
5.15 P.M. (Department of Pharmacology.) Mr. J. F. Daniel D.SC.: Cell Physiology and Pharmacology (first of s weekly lectures).
BRITISH ORTHOPÆDIC ASSOCIATION
9.30 A.M. (Washington Singer Building, University Colleg Exeter.) Mr. G. R. Girdlestone, Mr. Norman Capenc Mr. M. C. Wilkinson, Mr. J. P. Campbell, Mr. B. McFarland, Mr. J. A. Cholmeley: Surgical Treatment Tuberculosis of Bones and Joints.

Saturday, 26th

BRITISH ORTHOPÆDIC ASSOCIATION
10 A.M. (Royal Devon and Exeter Hospital.) Short papers.
MEDICAL SOCIETY FOR THE STUDY OF VENEREAL DISEASES, 1 Chandos Street, W.1
2.30 P.M. Sir Weldon Dalrymple-Champneys: Epidemiologic Control of Venereal Disease.

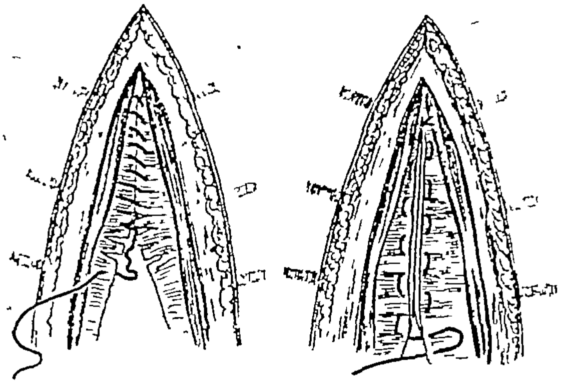
Secondly, fat is a store of fuel to be drawn on when od is lacking.

Thirdly, fat, combining the displaceable qualities of a uid with the permanence of a solid, is used as cushioning aterial, to bear weight, as over the heel and the tuber schii, to allow structures to move or change their shape a confined and rigid space, and to protect vessels and erves exposed to sudden angulation near a joint.

Fat has a scanty blood-supply and therefore a poor esistance to trauma and infection. It must be treated ently, cut cleanly, not torn or undermined. The fatty ayers of a wound should be drained under conditions of ontamination in which more vascular tissues could be rusted. Fat is on the whole the enemy of surgical handiraft. It tends to alternate with connective tissue in the interspaces of the body, such as the subcutaneous layers and the mesenteries. Where there is little fat there is much fibrous tissue and stitches hold well; where there is much fat blood-vessels have hardly any adventitious sheath, and tear easily or slip out of ligatures, and stitches tend to cut out.

CONNECTIVE TISSUE

Connective tissue is the framework of the body, the limiting agent that draws a boundary line between one structure and the next, the clothing agent that furnishes the uniform in which each organ serves, the strengthening agent that gives the necessary toughness to more specialised tissues. It provides the sheaths of muscles, nerves, and blood-vessels; the capsules and ligaments of joints; the envelopes of glands; the aponeuroses and tendons of muscles. It gives toughness to epithelial mucous and serous coverings and linings, whose surface cells give the special properties of lubrication, secretion, and resistance to infection. It is the only structure that holds stitches. Where there is no connective tissue, as in the brain, suture is impossible: where there is little, as in the liver and kidney, it is difficult. Connective tissue is a simple structure needing very little blood-supply. For this reason it is very viable and can be transplanted. For the same reason it has a low resistance to infection; but, since it usually occurs in thin sheets accompanying more vascular structures, it does not slough like fat. When infected it may take many months to sequestrate.



(a) (b)

Fig. 6—Suture of posterior rectus sheath: (a) over-and-over stitch; (b) running mattress stitch.

The properties of connective tissue as the basic material of surgical handicraft vary with its site and function. The derma is a felt-work, equally strong in all directions. It can and does stretch, and is therefore unsuitable for transplants where strength is desired. Tendons and aponeuroses consist of parallel fibres laid down in the line of strain and are strong in the line of their fibres but easily torn across it. The posterior rectus sheath and Poupart's ligament are examples of connective-tissue structures constantly encountered by the surgeon that are strong in one direction only. To obtain adequate access, the posterior rectus sheath must usually be divided across its fibres, and the cut edges therefore offer very little hold to sutures, which tear out if there is any tension (fig. 6*a*). Here a running mattress suture (where, instead of a single stitch pulling in the line of the fibres, a loop holds a bunch of fibres securely and everts the peritoneum) is the one workmanlike method of approximation (fig. 6*b*). No surgeon would willingly cut across Poupart's ligament, but all must use it as the inferior anchorage of any reconstruction of the inguinal canal. For such work, living sutures, such as pedicled strips of external oblique, and transplanted strips of fascia lata, have the considerable disadvantage that their necessarily coarse calibre splits the ligament into a leash of separated fibres. For these reasons many surgeons prefer foreign suture material of finer calibre. Where aponeuroses are felted, as are the layers of the rectus sheath at the linea alba, stitches hold well. Scar tissue is usually felted and gives secure anchorage.

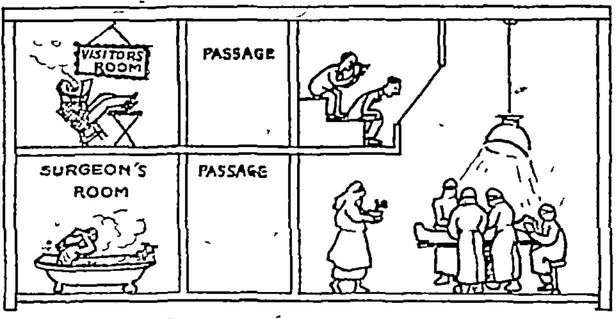


Fig. 7—Scheme for theatre and spectators.

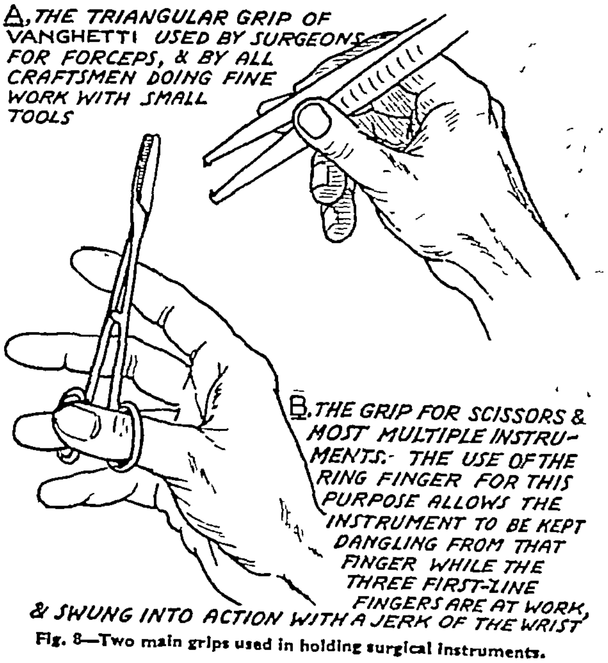
MUSCLE

Muscle, unlike skin, fat, and bone which are structural, is a functional tissue. Muscle which does not function because its nerve-supply is cut dies as surely as if it is deprived of blood. Muscular tissue has an abundant blood-supply on whose uninterrupted continuity its survival depends.

Free incisions into a muscle may lead to the death of a segment by cutting the vessels that supply that part;



A. THE TRIANGULAR GRIP OF VANGHETTI USED BY SURGEONS FOR FORCEPS, & BY ALL CRAFTSMEN DOING FINE WORK WITH SMALL TOOLS
B. THE GRIP FOR SCISSORS & MOST MULTIPLE INSTRUMENTS:- THE USE OF THE RING FINGER FOR THIS PURPOSE ALLOWS THE INSTRUMENT TO BE KEPT DANGLING FROM THAT FINGER WHILE THE THREE FIRST-LINE FINGERS ARE AT WORK, & SWUNG INTO ACTION WITH A JERK OF THE WRIST

Fig. 8—Two main grips used in holding surgical instruments.

The incision having been planned, care must be taken before making it to ensure that when sutured the two edges shall lie exactly as before. The elastic skin over any part tends to return to the position of rest, which is not necessarily the extended and supine position of a patient on the operating-table, and, when cut, the two edges may take independent directions (fig. 4). To ensure that they are brought together by suture as they lay before incision, they must be marked by lines drawn across the site of the cut before it is made. These marks are usually made by scratches, an effective method but a crude one, for the scratches often show permanently, and being in tension lines occasionally become keloid. They should be made with a dye such as Bonney's blue, drawn in bold strokes across the skin with a poster nib.

Sutures.—In suturing, the superficial fascia as well as the skin should be brought together accurately with a tension that keeps them in apposition but does not interfere with their blood-supply. The same stitch cannot bring the deeper layers together as well as the superficial unless it embraces them in a wide sweep, when it will be too far from the skin edge to secure exact epithelial apposition (fig. 5A). Methods that appose the skin edges exactly, particularly Michel's clips, leave spaces in the subcutaneous layers in which infection may appear, and which in any case leave a broad band of scar tissue in the deeper layers (fig. 5B). The use of separate suture for the subcutaneous and cutaneous layers is undesirable, for fat resents buried foreign material (fig. 5C). A continuous suture is easy and rapid, but is not accurate anywhere unless it is a blanket stitch, for the material is inserted as a spiral whose coils are nowhere opposite each other, and tightening approximates the ends of the incision, not its edges (fig. 5D). The best method is probably to insert a series of tension stitches at intervals of about an inch, including all layers and piercing the skin about half an inch from the incision, and to approximate the skin by other stitches between these (fig. 5E).

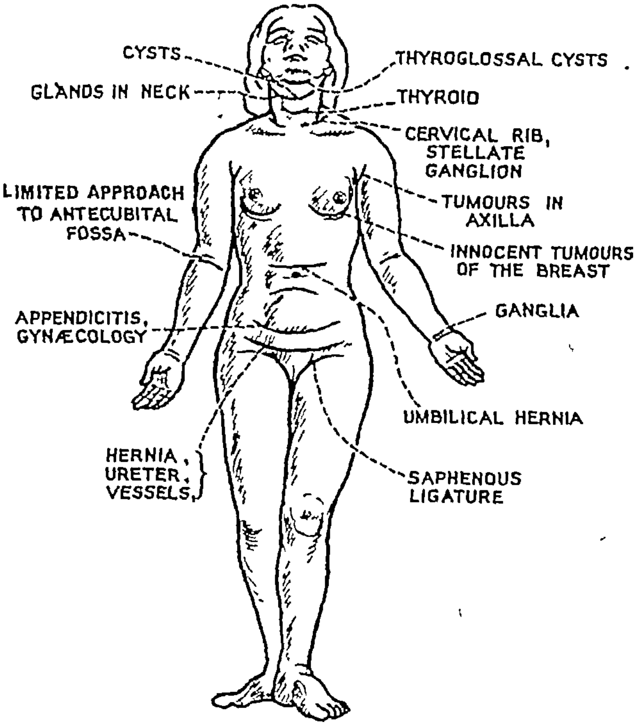


Fig. 3—Incisions.

Skin cannot be sterilised except temporarily and on its surface. Stitches passed through its thickness traverse the deeper layers, where sweat and sebaceous glands harbour resident organisms, and form a track along which these organisms may spread. Infection along a stitch track is largely mechanical. Suture materials with a mesh—e.g., silk, linen, and cotton—form a wick that absorbs tissue fluids, giving not merely a path to bacteria but also food for their journey. A thick strand makes a larger hole and is likely to perforate more glands and allow more bacteria through than is a fine one. The impervious monofilament suture materials are in theory the best, and in practice they seem to give healing with least reaction and to leave no stitch marks if they are removed early. The favourites of the moment, nylon and steel wire, both have disadvantages: nylon is not very strong, and will not tie securely with a single reef knot; and steel wire can only with difficulty be prevented from kinking. Fine selected silkworm gut is hard to beat.

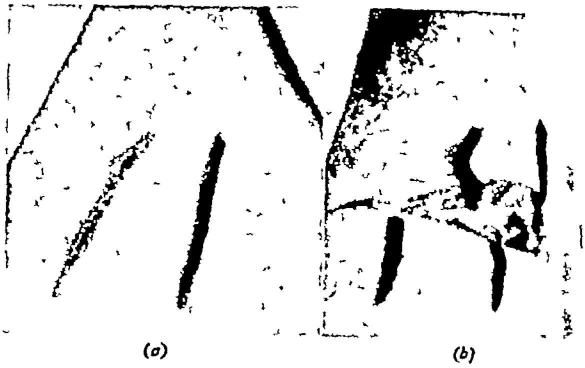

Fig. 4—Method of obtaining correct apposition of skin in suturing: (a) lines marked with dye before incision; (b) distortion of skin after incision.

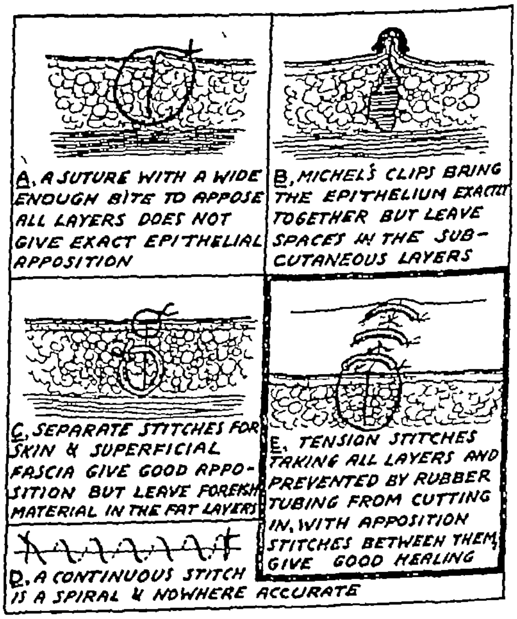
FAT

Fat in the body has three main purposes. First, it is a heat insulator. Man is almost unique among land mammals in using fat for this purpose. Other land mammals, indeed all warm-blooded creatures who live in the air, use the non-conducting properties of air for heat protection by trapping a layer of it round their bodies in fur or feathers, and by varying the thickness of the layer to suit the needs of the moment. The human being who loses his fat loses his human appearance. The very old man or the starved child looks like a monkey.



A, A SUTURE WITH A WIDE ENOUGH BITE TO APPOSE ALL LAYERS DOES NOT GIVE EXACT EPITHELIAL APPOSITION
B, MICHEL'S CLIPS BRING THE EPITHELIUM EXACTLY TOGETHER BUT LEAVE SPACES IN THE SUB-CUTANEOUS LAYERS
C, SEPARATE STITCHES FOR SKIN & SUPERFICIAL FASCIA GIVE GOOD APPOSITION BUT LEAVE FOREIGN MATERIAL IN THE FAT LAYERS
D, A CONTINUOUS STITCH IS A SPIRAL & NOWHERE ACCURATE
E, TENSION STITCHES TAKING ALL LAYERS AND PREVENTED BY RUBBER TUBING FROM CUTTING IN, WITH APPOSITION STITCHES BETWEEN THEM GIVE GOOD HEALING

INSTRUMENTS

In this workshop we do our tasks of incision, excision, pair, and reconstruction, and in doing them we must t, pick up, hold, crush, fix, and join the tissues which e our materials. Special instruments are needed to cut, ld, and fix bone with its special properties; for the ke of brevity and simplicity we will leave these out id consider only the craft of soft-tissue surgery. In is we use a knife to cut skin, and scissors to cut fascia sutures; dissecting forceps to pick up; tissue forceps r a gentle hold, and hæmostats for a firm one; Ochsners hold or crush, and needles to sew. These are our basic tools, though we must have others, such as towel-clips and needle-holders, and a few one-purpose tools for special jobs.

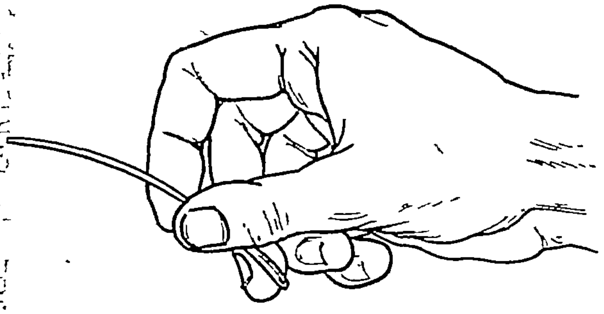

Fig. 13—Three-finger grip for hand sewing.

The aim of every craftsman should be to do the best work he can. Skill comes with repeated performance, and a surgeon can increase the number of times he does any particular thing either by doing everything more often or by limiting the number of things he does. The second alternative is the more practicable. He can limit the number of different instruments he uses and limit the types of movement his hands are called on to perform.

Two movements are in constant use in surgery: the opposition of the thumb to the index and medius, with which spring tools, such as dissecting forceps, are held (fig. 8A); and the abduction and adduction of the thumb opposite the radial side of the curved and fixed index, medius, or annularis, with which hinged instruments, such as scissors, hæmostats, and needle-holders, are opened and closed (fig. 8B). By limiting his designs to these two movements, the surgeon can hope to make his fingers automatically dexterous; but, if he uses needle-holders that close with a whole palm grip and open with a further squeeze, or dissecting forceps that open with pressure and close with a spring, he tends to confuse the association-centres of his parietal cortex.

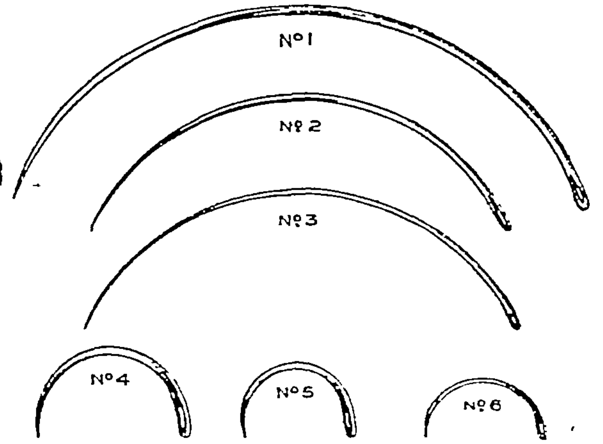

Fig. 14—Standard needles.

Having selected his design, he should decide on the pattern, weight, length, and curve of each that is most suitable to his requirements, and see that only these are given to him when he operates. To be put off with an odd assortment, to accept different patterns at different hospitals, is to abandon all hope of acquiring that instinctive control of the working end of his tools that is the hallmark of a skilled craftsman.

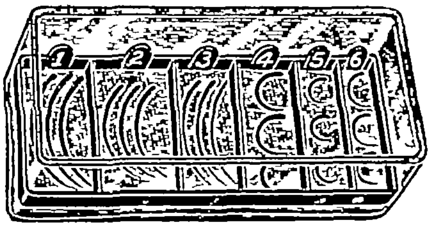

Fig. 15—Needle grid and box.

Cutting Instruments.—Surgical knives are as traditional as the black silk scarf of the sailor, which was introduced to protect his collar from the grease on his pigtail. The shape is that of the sword or dagger, an instrument designed in the Bronze Age to stab but only occasionally to cut (fig. 9A). A knife cuts with its edge, and a straight knife should therefore be used only to cut a rounded surface (fig. 9B) raised to waist level, such as a ham, a loaf of bread, or a limb to be amputated, or to take a shaving from a flat surface in the horizontal plane, as in skin grafting. In most surgical manœuvres the knife is held at about 30° to the surface to be cut, so that the effective edge is a short section near the tip, beyond which the point projects to an unknown depth (fig. 9C). Surgical manufacturers have tried to introduce sense without offending tradition by making a knife with a rounded belly (fig. 9D), but this is no more than a timid move in the right direction. The correct blade was designed shortly before his death by Cecil Joll, and is made by Gillette Bros.; it fits a Bard-Parker handle and, when held in the usual working position, its cutting edge is parallel to the skin (fig. 9E).

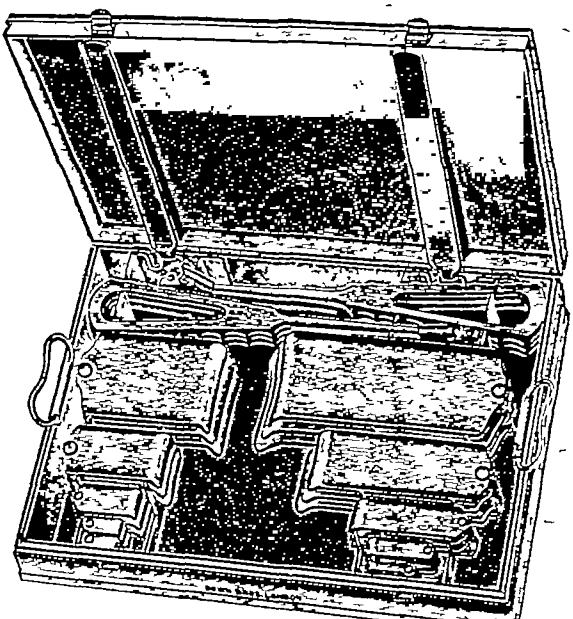

Fig. 16—Detachable retractors in case.

Holding Instruments.—These must pull structures out of the place in which they lie and to which they tend to return. They must therefore take a grip, which will rough handling and strangulation by sutures tightly tied may do the same. On the other hand, muscle with its free blood-supply offers a high resistance to infection, and its cut surfaces heal rapidly if approximated without tension or strangulation. Septic conditions in the abdomen should therefore be approached by incisions through muscles rather than through fibrous planes. A colostomy should be brought out through muscle to avoid sepsis and fibrosis. Muscle cannot be transplanted as a free graft, but a strip whose blood-supply is preserved may be swung as a pedicled graft to fill a cavity.

BONE

Bone is specialised connective tissue and has many of the same properties: the strength, the ability to hold fixing materials, the low blood-supply, the poor resistance to infection, the transplantability. It differs in being rigid. It cannot be bent, and a bone surface can be approximated to another surface of bone or soft tissues only if the two are a mechanical fit. Its properties are partly those of hard wood, like oak or teak, partly those of stone or concrete. Long bones and young bones are more like wood, square bones and old bones like concrete.

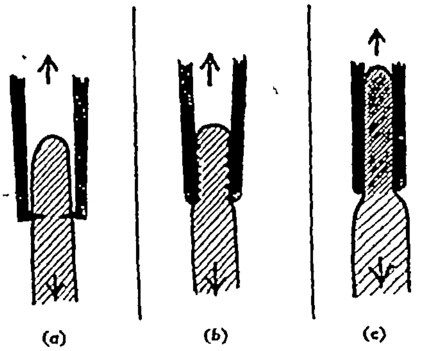

Fig. 10—Holding instruments: (a) instrument with points can grip without pressure; (b) instrument with serrated jaws can grip with light pressure; (c) smooth instrument can grip only with strong pressure.

OPERATING-THEATRE

These then are our main materials; what of our workshop, the operating-theatre? The design is a matter of functional needs, individual preference, and architectural fashion, but it must meet certain requirements. The air in the immediate neighbourhood of the wound must be sterile or at least free from pathogenic organisms, and the temperature must be warm enough to conserve the body heat of the patient, yet cool enough to allow the team to work without exhaustion. The lighting must be adequate and dirigible on the operating field from all points of the hemisphere above it.

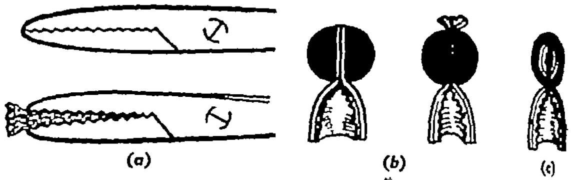

Fig. 11—Forceps blades: (a) above, forceps with blades closed; below, forceps with blades forced apart by included tissue; (b) hold given by blades of normal design; (c) hold given by blades of trap-jaw pattern.

The first essential in an operating-block is that the theatre and its annexes must be accessible only to sterile materials and "sterile" personnel, that is to the patient and the operating team. Spectators must be on another floor reached by another staircase or lift (fig. 7). This arrangement not only avoids unnecessary contamination of the air and furniture of the theatre but also gives better facilities for instruction. The spectators' gallery, sealed off from all air communication, can be brought right over the operating-table so that the visitor can look into the depths of the wound instead of over its edge, as he does when he stands beside the team, and with field glasses he can see detail as well as the surgeon can. In the near future television installed in the lamp assembly will allow any number of spectators to get the same view. The separate gallery does more than reserve the theatre for its proper purpose; it becomes part of an instruction floor where demonstrations and exhibitions can be arranged for visitors between operations.

The air on an upper floor, where theatres are usually built, is practically free from organisms. Airborne infection comes from dust, which in turn accumulates on projecting fittings and is distributed by air currents, and from droplet infection. Fittings, such as cupboards, stoves, and shelves, have disappeared from any modern theatre, and those that remain, such as X-ray viewing screens and electric fittings, can be flush with the walls. Many of the projections that accumulate dust, and many of the air currents that distribute it, are bound up with the lighting, ventilation, and warming of the theatre. Air-conditioning, serving at one time the needs of ventilation, temperature regulation, and air purification, solves most of these problems, since pipes and hot panels disappear and air currents are diminished and predictable. Whether windows should disappear is debatable, but they probably will. Daylight is inferior to a properly designed lamp, and it cannot be laid on or varied at will. A lighting system can be exteriorised, and the only furniture that must remain in the theatre is the operating-

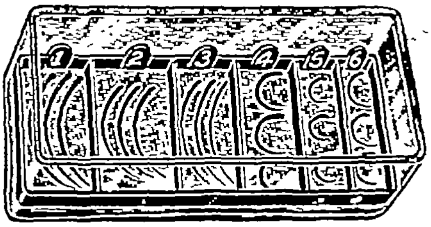

Fig. 15—Needle grid and box.

Cutting Instruments.—Surgical knives are as traditional as the black silk scarf of the sailor, which was introduced to protect his collar from the grease on his pigtail. The shape is that of the sword or dagger, an instrument designed in the Bronze Age to stab but only occasionally to cut (fig. 9A). A knife cuts with its edge, and a straight knife should therefore be used only to cut a rounded surface (fig. 9B) raised to waist level, such as a ham, a loaf of bread, or a limb to be amputated, or to take a shaving from a flat surface in the horizontal plane, as in skin grafting. In most surgical manœuvres the knife is held at about 30° to the surface to be cut, so that the effective edge is a short section near the tip, beyond which the point projects to an unknown depth (fig. 9C). Surgical manufacturers have tried to introduce sense without offending tradition by making a knife with a rounded belly (fig. 9D), but this is no more than a timid move in the right direction. The correct blade was designed shortly before his death by Cecil Joll, and is made by Gillette Bros.; it fits a Bard-Parker handle and, when held in the usual working position, its cutting edge is parallel to the skin (fig. 9E).

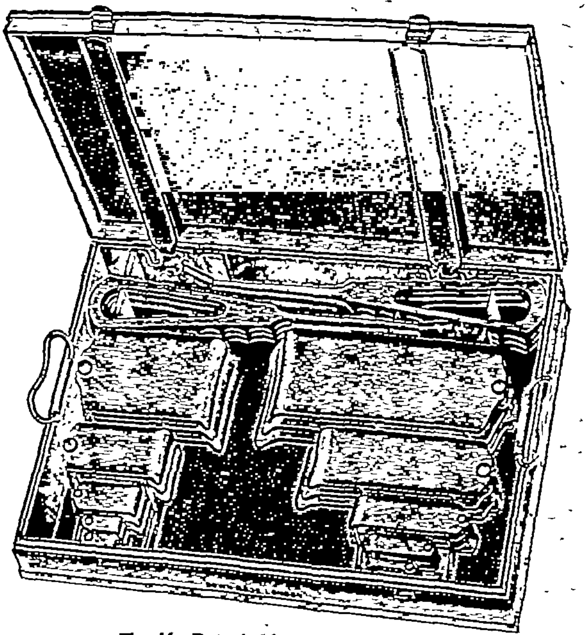

Fig. 16—Detachable retractors in case.

Holding Instruments.—These must pull structures out of the place in which they lie and to which they tend to return. They must therefore take a grip, which will

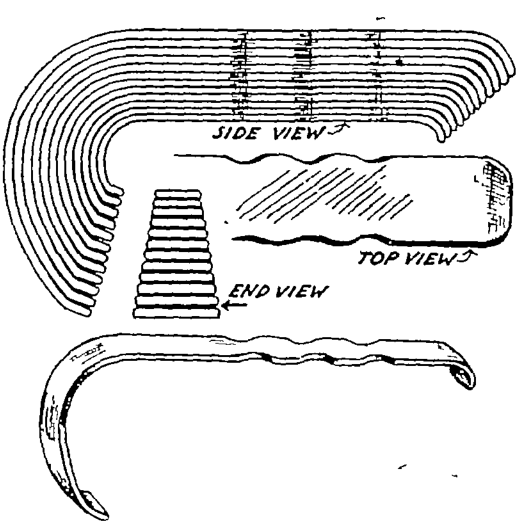

Fig. 17—Nested retractors of new design.

depend for its security either on surface friction or on *contour deformation.* The better the surface grip, the less need there is for deformation—i.e., for pressure. Instruments intended to hold tissues gently must therefore be able to grip their surface, or even have points to prick it (fig. 10*a*), for a small prick does much less harm than a wide or heavy crush. A stitch through the tongue will hold it out with little damage, a spade-shaped tongue forceps will leave it bruised for days. Intestinal clamps have been carefully designed with little ridges, like the papillary markings on a finger-tip, to hold intestine firmly without undue pressure (fig. 10*b*); if the blades are covered with rubber tubing they must be closed to the point of ischæmia to give the same grip (fig. 10*c*). When damage to included tissue is intended or unimportant, holding and crushing become synonymous. Holding forceps, such as hæmostats, Mayo-Ochsners, or gall-bladder forceps, depend for their security on the forcible apposition of their jaws. When hinged blades are applied forcibly they are kept apart by the tissue compressed between them in a gap which is wedge-shaped, holding the gripped tissue firmly at the hinge end and less firmly towards the points (fig. 11*a* and *b*). Even when the surfaces are roughened or corrugated they are unable to hold securely a tube like the duodenum, the appendix, or the cystic duct, if it is cut off flush with the blades. Only when a flange of uncrushed tissue is left projecting beyond is the hold safe. I have lately redesigned my holding instruments on what I call the trap-jaw principle. The blades are hollow, with a narrow rounded rim. The rim holds a strip of tissue in compression, while the hollow accommodates an uncompressed part that prevents slipping in the same way as does a projecting flange of tissue in the usual design (fig. 11*c*). The trap-jaw principle has been applied to dissecting forceps, hæmostats, V Ochsners, and gall-bladder forceps.

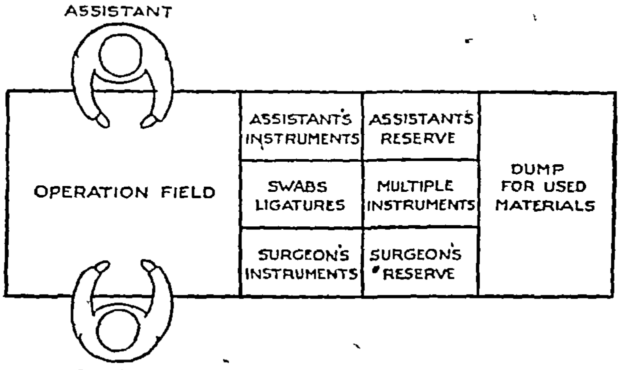

Fig. 18—Lay-out of operating-table.

With hæmostats we must also consider the curve. in the knife, they should be so designed that thei end is correctly aligned when the surgeon's hand arm are in their position to function. A hæmostat used either for picking up small vessels, when its p are applied at right angles to a surface, or for wide oozing areas, when its blades are closed p to a surface. For both purposes a straight instrument wrong. A straight instrument is suitable for transmitt a push or a pull in its long axis ; one that is used for m skilled purposes is given a functional inclination. arrow, a spear, and a ramrod are straight ; a scythe golf-club, a hockey-stick, a spoon, and a fork are curv An aspirating needle must be straight to push and a ti forceps or Mayo-Ochsner to pull, but a hæmostat sho have a curve or angle of about 30° on its blade, to ma it suitable, like a fork, for application in either pla (fig. 12).

Sewing Instruments.—Sewing is one of the m important tasks in surgery and, for a man, one of t most difficult. It is therefore one in which the surge must at the outset select his methods and his instr ments, so that he may by repetition ultimately co within reasonable distance of the skill with which his wife darns his socks.

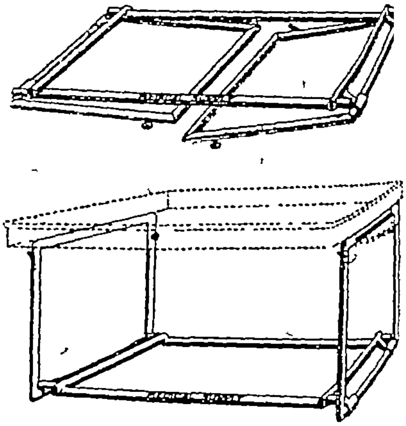

Fig. 19—Folding stand for tray.

First he must decide whether he intends to be a hand sewer or a user of needle-holders. Every surgeon must be prepared to work with a small curved needle and a needle-holder in inaccessible places. Many, particularly those who have the whole-time service of an expert theatre team, prefer to use a needle-holder for all sewing, since it uses the same movement, a half-turn of the wrist, all the time.

The man who prefers interrupted sutures likes to work with a needle-holder. The surgeon who works with a continuous suture prefers sewing with his fingers, which brings him nearer his work by the length of a needle-holder and gives a more delicate control of the movements of the needle point and a more accurate estimation of the tension of the sutures. Hand sewing is on the whole neater and faster.

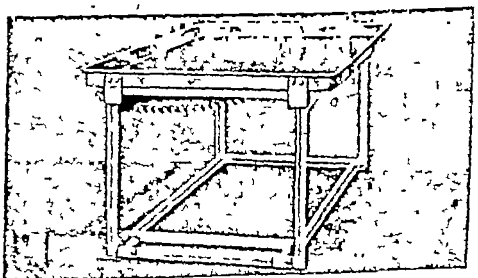

Fig. 20—Instrument tray and stand.

Having decided his method, the surgeon must select the shape, diameter, and length of the needles he will use. For hand sewing a straight needle should be the best. It is the shape that women use. It is propelled by a thrust along its length ; and, while it is being propelled, e direction of its travel and the site of its point are actly known. But women have their sewing on their ps, and they work on fine flexible fabrics. A straight needle cannot be used in the depths of a wound, and it can be made to take a small bite only if the tissue through which it is being thrust is folded. Curved needles may be of any length, diameter, or curve. The more open the curve, the more do they partake of the advantages and drawbacks of a straight needle—i.e., the more easily are they propelled, the less are they suited to taking up a small bite of tissue and to working in a hole.

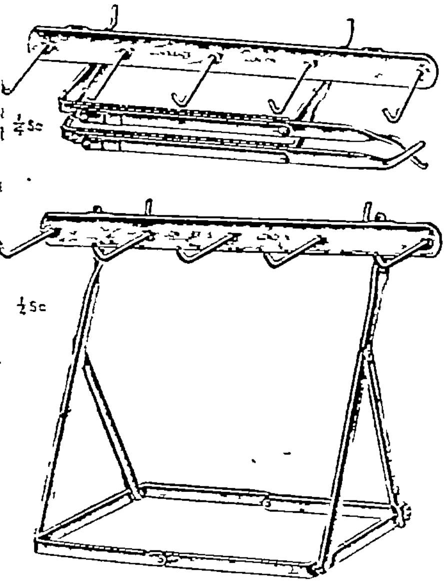

Fig. 21—Instrument rack.

The shape of a needle concerns the surgeon. The diameter affects the tissues through which it passes and the suture material that passes through it. A fat needle is the tool of a fat-head; it makes big holes and is no stronger than a thin one made of good steel. Needle makers seem to work on a scale of gradations, their needles of any particular pattern increasing in thickness as they do in length, so that the larger sizes are quite needlessly coarse. The correct diameter of a needle is that which will carry an eye that is an easy fit for the thickest suture material to be used with it. An eye that is only just large enough makes the suture stand out on each side and tear the tissues; one that is too large allows it to drop out.

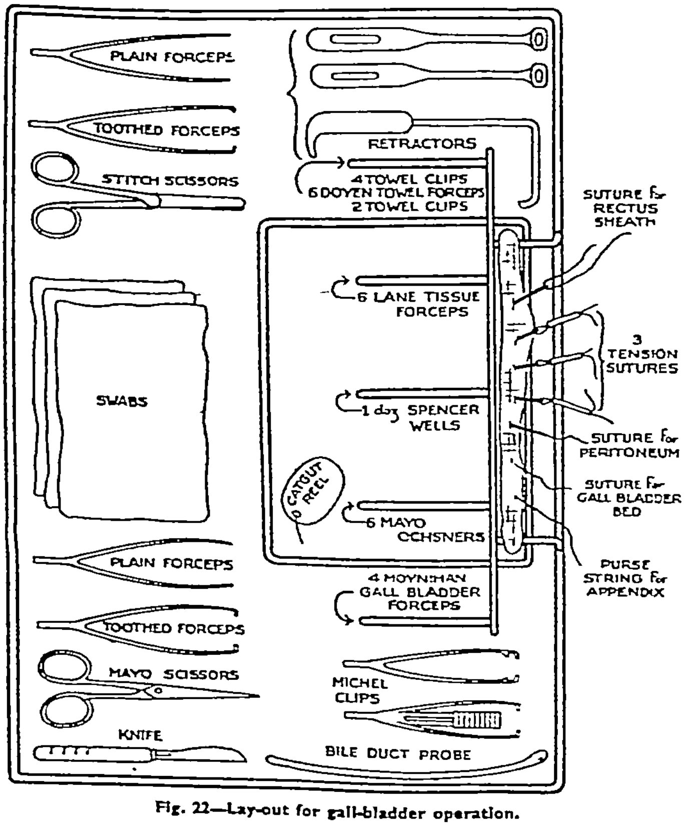

Fig. 22—Lay-out for gall-bladder operation.

A needle must be long enough to take a reasonable bite of tissue, while at the same time enough of the eye end remains behind to be held, and enough of the point projects beyond to be grasped. If a reasonable bite of tissue is assumed to be $^{1}/_{4}$ in., a needle for use with a holder requires at least another $^{1}/_{4}$ in. proximally and distally to be grasped with the needle-holder, whereas one worked with the fingers requires $1^{1}/_{4}$ in. proximally to allow the three-finger grip (fig. 13) which is necessary for accurate control, and 1 in. distally to be seized with the fingers. A needle for use with a needle-holder has therefore a minimal length of $^{3}/_{4}$ in., and one used for hand sewing a length of $2^{1}/_{2}$ in.

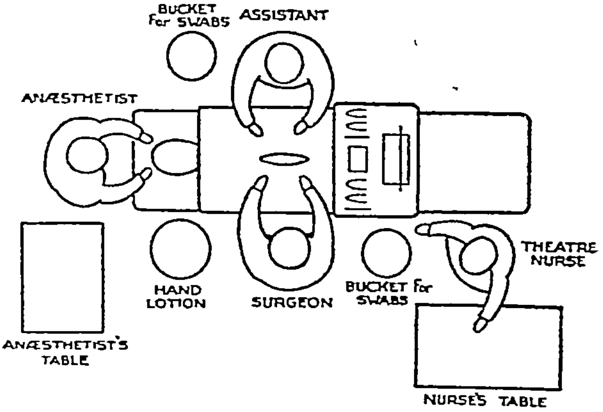

Fig. 23—Arrangement of theatre.

I decided many years ago that for hand sewing a $^{3}/_{8}$ circle was best, a compromise between the straight and the curved: straight enough for control, curved enough for use in a deep wound. I required three needles all having the same length and curve: no. 1 triangular pointed to take stout silkworm gut; no. 2 round-bodied to take no. 1 catgut for peritoneum, aponeuroses, and soft tissues; and no. 3 to take 00 catgut for intestinal suture. All standard needles (fig. 14) of this length and curve were absurdly stout, and the patterns I required had to be specially made. For use with a needle-holder I chose three half-circle needles: no. 4 to take no. 1 catgut: no. 5 to take 00 catgut: and no. 6 a cutting needle for use with gossamer silkworm gut. The small needles have a flattened shank beyond the eye, so that they do not turn in the needle-holder. These six needles have now been standardised for ten years and are sold by the Medical Supply Association Ltd. as Ogilvie needles 1 to 6.

Having elected to work with needles of two shapes only, I found that the two groups of three, each roughly of the same length and curve, tended to confuse sisters unaccustomed to working with me. To solve this difficulty I ordered a small plated frame with numbered compartments that can be dropped into any needle-box (fig. 15). Each needle lies in its own compartment, and now, when I ask for no. 3 needle in Southwark or Somaliland, I get the exact curve and diameter I have been using since 1930.

Retractors.—A lesser difficulty, but one that must be faced, is the selection of retractors. An operation that is difficult without adequate retraction becomes simple if the right retractors are available. The right retractor is one exactly suited in width and depth to the tissues to be retracted. To provide all the retractors that may be wanted for every stage of every operation is almost beyond the resources of the average hospital, and to have the right one available just when it is wanted will tax the ingenuity of even the best theatre sister. The answer lies in a graded set that can be nested together. Nine years ago I designed a set of retractors with detachable blades and handles (fig. 16). This set is nested in a tray and can be sterilised and kept on a corner of the instrument table, ready to make up any retractor that is demanded. This year I have produced a simpler set of retractors of the curved shape usually known as Deavers (fig. 17). This is easier to make and therefore cheaper than the detachable set, and it provides twelve retractors: the largest suitable for resections of the rectum; the intermediate for gall-bladder or stomach surgery; and the smallest for operations in the neck or on the limbs.

LAY-OUT

The craftsman has the job on hand on his bench. Two or three tools with which he is working at the time are in his hand or beside him; the remainder are in shelves, trays, or racks close at hand, each with its own labelled place to which it is returned after use.

The surgeon's work-bench is his operating-table, and his material the body of the customer who has brought him the job to do. For tidy work, the table with the patient on it should be divided into three zones: the operation field, the reserve of instruments, and the dump (fig. 18). The first should contain only those instruments in use at the time; the second corresponds to the carpenter's tool rack and carries all the instruments and materials that may be wanted; the third is for soiled or discarded implements. The instrument zone is further subdivided into six areas: one side belongs to the surgeon, one to the assistant, and the middle is common ground, while each of these territories has a front half for things in constant use, and a back half for reserve instruments.

The technical problems involved are the provision of a stable platform for the instrument zone, and the arrangement on that platform of all the different things that may be required. They have been solved in my workshop by the stand, the tray, and the instrument rack. The stand (fig. 19) is a simple tubular frame that folds flat for transport and lies under the rubber mattress of the operating-table, with the sides hanging down when not in use. It can be put at any part of the table suited to the operation, and when erected forms a rigid support for the tray (fig. 20). The tray is an aluminium rectangle with sides 1 in. high, carrying underneath four angle-pieces to fit the sides of the stand. The instrument rack (fig. 21) consists of a horizontal bar carrying five pegs facing forwards and two short ones facing backwards. This bar is supported on trestles springing from a rectangular frame which serves as a base. The whole folds up for sterilising but is rigid when put together. The instrument rack serves as a magazine for multiple instruments, towel-clips, tissue-forceps, hæmostats, and so on, whose proper place is in the back half of the intermediate zone. The back pegs are intended to take a strip of gauze in which threaded needles can be placed ready for the surgeon. The exact arrangement of materials on the tray and of instruments on the rack is a matter for individual preference, and the diagram (fig. 22) of my own arrangement for a gall-bladder operation is merely intended to show the equipment in use.

In practice the system allows the team to have in the operation area only the tools actually being used and one clean swab apiece. When an instrument is finished with, it is laid in its place on the tray if a "first-line" instrument (knife, scissors, dissecting forceps, ligature reel), and given to the nurse if it is a multiple instrument or dirty. The nurse's duties are merely to see that the stock of swabs and ligatures in the intermediate zone is replenished, to wash instruments given to her and return them to their appropriate place or peg, and to have threaded needles ready (fig. 23). The surgeon used to the system gets precisely the same service wherever and with whomsoever he works. He comes to know the place of everything by instinct and, without taking his eyes off the wound, can reach out and get the exact instrument he wants.

ENVOI

These are the materials and the tools of our craft. We shall undertake more ambitious tasks as new discoveries bring better tools and methods to our workshop, and we shall do them better as craftsmen from all countries pool their designs and their experience. But our aims must remain the same: to treat each customer as if he were the most important man in the world, and to do the job he entrusts to us as well as we can; to divide tissues cleanly and gently, so far as possible along anatomical planes; to forestall hæmorrhage by seizing every vessel as it is encountered and by ligaturing it with the finest material; and to close the wound by anatomical reconstruction and to obliterate all dead space without tension or strangulation of living tissue by tight sutures. Our patients should return to bed showing no more than the normal physiological reaction to trauma, a reaction from which they will recover in a few hours. Our wounds should heal without incident. Our scars should be a pink hair-line in ten days and should be invisible in three months. Gentleness should be instinctive in one who is fitted for the craft of surgery, for the gentle surgeon is a gentle man; he treats tissues kindly because he feels instinctively for their suffering.

SURVIVAL OF VARIOLA VIRUS IN DRIED EXUDATE AND CRUSTS FROM SMALLPOX PATIENTS

A. W. DOWNIE
M.D., D.Sc. Aberd.
PROFESSOR OF BACTERIOLOGY

K. R. DUMBELL
M.B. Lpool
LECTURER IN BACTERIOLOGY

UNIVERSITY OF LIVERPOOL

THE dried crusts from the skin lesions of smallpox patients are usually regarded as an important source of infective material in the dissemination of smallpox (Ker 1909, Rosenau 1922, Stallybrass 1931). Blaxall (1930) states that the separating crusts remain potentially infective for years. It has been shown experimentally that the closely related animal pock viruses are relatively resistant to drying, but the evidence for the survival of variola virus in crusts from human lesions rests largely on epidemiological observations. Until recently, experimental work with variola virus taken directly from human sources was limited in scope, because monkeys were the only highly susceptible animals available.

Since it has been shown that variola virus can readily infect the chorio-allantois of developing hens' eggs (Lazarus et al. 1937), and that it produces in this tissue highly characteristic lesions (Downie and Dumbell 1947), the technique of egg inoculation appeared to afford a ready means for determining directly the infectivity of variola virus in material from human cases. In the observations recorded here egg inoculation has been used to determine the period of survival of variola virus in crusts and exudates kept under ordinary atmospheric conditions at room temperature (18°–20° C).

MATERIAL AND METHODS

These observations on survival of virus in crusts were begun in the spring of 1946, when several outbreaks of smallpox occurred in England, the infection being introduced from abroad, mostly by Service men who developed the disease, often in atypical form, on the way home.

Most of our material was derived from the cases which occurred in the 1946 outbreak on Merseyside (see Peirce 1947). We also had available in the laboratory samples of crusts from one of the cases in the Middlesex outbreak of 1944 (Bradley et al. 1946) and from two cases which occurred at different times in 1945.

Diagnostic complement-fixation tests had been made with extracts from the crusts at the time they were received, and the rest of these samples were kept in a desiccator in the refrigerator at a temperature of 2°–4° C until they were tested for the presence of virus in 1946.

In the 1946 outbreaks specimens of crusts were received from patients at various stages after the onset of illness (see table IV). The crusts were usually kept in the refrigerator without desiccation for some days and then were left at room temperature in the laboratory and tested at intervals thereafter.

Where the specimens were sufficiently large they were divided into two lots: one lot was placed in a test-tube or wide-mouthed bottle loosely stoppered with cotton-wool and kept in a cupboard; the other was placed in a similar container and exposed to diffuse daylight on the sill of a window facing north-west.

At intervals, from three to ten crusts were removed, thoroughly broken up in a sterile test-tube with a glass rod, and 1·0 ml. of sterile buffered distilled water was added. This suspension of crust material was left to extract, with stirring at intervals, for two hours at room temperature and then in the refrigerator overnight.

Next day the suspension was centrifuged for one minute at low speed in an angle centrifuge, and the supernatant fluid was mixed with an equal volume of penicillin solution, 300 units per ml. to suppress bacterial contaminants before inoculation on the chorio-allantois of two or three fertile hens' eggs.

In diagnostic tests reported elsewhere (Downie and Dumbell 1947) we had found that living virus could be recovered by egg inoculation from smallpox-vesicle fluid which had been smeared on glass slides and sent to the laboratory for microscopical examination. We made further tests on one sample of fluid dried in this way. This specimen had been taken with a capillary pipette from the skin lesions in a patient with hæmorrhagic smallpox on the seventh day of disease, one day before death.

The specimen was small, measuring about 0·05 c.cm. and was diluted to 0·5 c.cm. in broth on receipt at the laboratory. The diluted fluid was kept in the refrigerator for 17 days in a small screw-capped bottle. Human serum from a healthy young adult who had never been vaccinated was then added to make 20% by volume. The fluid was dropped from a pipette on a series of sterile glass slides and, after the drops had dried in air, the slides were placed in sterile petri dishes, some of which were placed in a cupboard and the others on the window sill.

At intervals afterwards the material from the drops was taken up in distilled water and after admixture with an equal volume of penicillin solution, 300 units per ml., the fluid was inoculated on the chorio-allantois of developing hens' eggs, as with the crust extracts.

The technique of inoculation on the chorio-allantois was that commonly used (Beveridge and Burnet 1946). Before inoculation the eggs were incubated at 37° C for 12 days. The inoculum was in each case about 0·1 ml. in volume, and the inoculated eggs were examined after two or three days' further incubation at 36° C.

When infection with variola virus occurred, the appearances on the membranes were typical and have been described elsewhere (Downie and Dumbell 1947): when the amount of virus in the inoculum was large, there was usually a spreading area of thickening and opacity which often covered most of the exposed chorio-allantois (confluent lesions); in other membranes a small central area of inflammatory thickening was surrounded by numerous discrete lesions (semiconfluent lesions); and in less heavily infected membranes the specific lesions were discrete and variable in number.

We have considered the number of such discrete lesions as proportional to the amount of living virus in the inoculum, and have recorded the number of lesions in such tests below. Where the lesions were few, or any doubt about their nature was entertained, the membranes were excised and ground up with glass, and after suspension in broth the supernatant fluid was inoculated on further eggs.

In only one instance, where two isolated lesions were present, did we fail to confirm the presence of virus in membranes which appeared to show typical variola lesions. Nor did we ever recover virus by further inoculation from membranes which did not show typical lesions after inoculation with crust extracts or resuspended dried vesicle fluid.

Where previous tests on a particular lot of crusts showed that very little living virus appeared to remain, several samples were taken and tested in parallel. This seemed more likely to lead to the detection of small amounts of residual virus than would the testing of a single extract from a larger sample of crusts.

RESULTS

Survival of Virus from Vesicle Fluid

The results of the tests on the vesicle fluid taken from one patient and dried on glass slides are shown in table I. The number of eggs inoculated with the resuspended dried vesicle fluid varied at different examinations according to the number of eggs available; and, though there was some irregularity in the results, table I indicates that the amount of virus surviving in the dried material diminished progressively up to 30 days, when very little remained. At subsequent examinations two drops were used, except in the last test, when the remaining four drops were used in each case. Though only one and two lesions developed on two membranes inoculated with the material kept in the dark for 84 days, passage to further eggs gave typical confluent infections, demonstrating the specific character of these lesions.

Survival of Virus in Crusts

Specimens of crusts from five cases of smallpox were kept at room temperature for periodic examination. Table II shows the results with a specimen which was kept at room temperature in the dark for more than six months. These findings indicate a gradual diminution in the amount of living virus during the first 100 days of observation, and on subsequent examinations the amount of virus demonstrated was very small. At this stage the results, as might be expected, were rather irregular. The negative finding on the sample removed after 111 days may have been due to chance selection of negative crusts, to insufficient trituration of the crusts, or to some other minor variation in technique. No further tests were made on this specimen after 202 days.

The crusts from one case taken on the 24th day of illness had been kept in a screw-capped bottle in the refrigerator for 145 days before observations were begun. The specimen was then examined in the usual way for virus and divided into two portions, which were placed at room temperature, one exposed to light, and the other in the dark. The results are shown in table III. The last test made on these crusts after 196 days again shows, as in table II, the variation which may occur with different samples taken at the same time from one specimen. There appears to be little difference in the time of survival between crusts kept in the dark and those exposed to diffuse daylight in a glass container.

The day on which virus was last recovered from the other three specimens of crusts are shown in table IV, which summarises all the results. The specimens from case 5 were tested after they had been kept 138 days and again after 167 days (three samples from each), but virus was not recovered. These crusts were lighter and softer in texture than the others, and this may explain the shorter period of survival of the virus as determined by our technique. Extracts from the crusts from case 3 did not produce lesions on three eggs after 141 days; but after 152 days the remaining crusts were divided into six lots; and, of the extracts prepared from these, three produced specific lesions on eggs, while three did not. The crusts of case 4, which showed the longest period of survival, had been kept in a dark cupboard throughout. After 328 days four samples each gave a few discrete lesions; after 396 days two samples were positive, and two negative; after 417 days one large sample of 24 crusts, which had been very finely ground before extraction, produced after 3 days 57, 26, and 51 discrete lesions on three membranes. No further tests have been made on this specimen.

Survival of Virus at Low Temperature

Although we made no experiments designed to test the period of survival of virus in crusts and vesicle fluid at low temperatures, it seems a priori highly probable that the period of survival at lower temperature would be longer than at room temperature. Such observations as we have made in the course of our work support this belief. Three specimens of crusts which had been stored in vacuo over calcium chloride were tested for virus after 202 days, 1 year and 43 days, and 2 years and 52 days. The third specimen, from a case in the Middlesex outbreak in 1944, gave confluent infections on egg membranes, and the others showed numerous discrete lesions. Part of the sample of vesicle fluid from case 1 (table I), which had been diluted in broth and kept in the refrigerator in a screw-capped bottle, gave confluent infections on egg membranes after nine months. A saline extract had been made from the crusts of case 4 (table IV) for serological tests soon after the crusts were received in the laboratory. Part of the saline extract which had been kept in a rubber-stoppered tube in the refrigerator for 1 year and 67 days produced 10, 31, and 87 specific lesions on three egg membranes. This result did not surprise us, as we had in December, 1945, recovered by culture on the chorio-allantois two strains of cowpox virus which had been stored in the form of concentrated elementary body suspensions in dilute buffer solution at a temperature of 4°–10° C since April, 1938, and February, 1939, when they had been prepared from dermal infections in the rabbit. Buddingh (1938) has noted that vesicle fluid from a case of smallpox was infective for the chorio-allantois after 5 weeks at 0° C, and North et al. (1944) record the recovery of virus by egg culture from smallpox crusts which had been kept at −8° C for one year.

DISCUSSION

In general our results show that in crusts and dried vesicle fluid kept at room temperature the amount of virus recoverable by infection of the chorio-allantois of developing hens' eggs diminishes at first fairly rapidly, but that virus can be detected many months after this initial period. The results in tables I, II, and III indicate some irregularity in our findings during the later periods, when the virus was less readily detected. This irregularity was evident especially when several samples were tested from the same specimen at one time, and may have been due to the irregular distribution of residual virus among crusts and to variation in the fineness of dispersion and degree of extraction of individual samples. It seems likely that repeated further examinations of our specimens using larger numbers of eggs would have shown the survival of variola virus for longer periods than those shown in table IV. The virus did not apparently survive so long in the diluted vesicle fluid which had been dried as thin films on glass slides as in crusts, and the nature and character of the crusts may be important in determining the period of survival of virus. It has been

TABLE IV—SURVIVAL OF VARIOLA VIRUS IN DRIED VESICLE FLUID AND CRUSTS AT ROOM TEMPERATURE

* Not tested later.

ted above that the crusts of case 5 were large, lighter, d softer than the others; the specimens from cases 4 d 6 both consisted of rather smaller, harder, and denser seeds," which may offer better conditions for the eservation of living virus.

There appears to be little relation between the virus ontent of crusts and the stage of the disease at which ey were collected; at least our findings showed that e crusts of case 6, collected on the 24th day of illness, pparently contained virus in amount comparable to at in crusts removed from other patients on the 10th–5th day of illness. Virus therefore survives in the skin sions of these patients after the immune state has ecome established.

Exposure to daylight seemed to have little influence n shortening the period of survival of virus in crusts tables III and IV); but in these tests the virus was rotected by tissue protein and shielded from ultraviolet adiation by the glass containers.

Though we have no information about the relationship between the infective dose of virus for the chorio-allantois and that for susceptible human beings, our findings confirm what has long been believed, that the material from the skin lesions in smallpox patients is infective. That such material has been responsible for the spread of smallpox there can be no doubt, and Stallybrass (1931) has recorded several instances of outbreaks among laundry workers where the infective material was conveyed on bedclothes. We have, by the egg technique, isolated virus from the sweepings from the ward floor near a bed in which a child was convalescing from smallpox. Such infective "dust" is a potential source of infection. We cannot regard the skin lesions as the only source of infective virus, for patients may spread infection before the skin lesions have developed; at this stage, and probably also later, the upper respiratory tract must be regarded as an infected region from which virus is disseminated.

SUMMARY

The chorio-allantoic membranes of developing hens' eggs, which are susceptible to infection with variola virus, have been used to detect the presence of virus in vesicle fluid and crusts from smallpox patients.

By this means virus was found to survive in diluted vesicle fluid dried on glass slides for 35 days when exposed to daylight, and for 84 days when kept in the dark at room temperature.

Virus was recovered from different samples of crusts kept at room temperature for several months, and from one specimen kept thus for over a year.

In crusts exposed to daylight virus survived as well as in crusts kept in the dark.

The bearing of these observations on the spread of smallpox is briefly discussed.

We wish to thank Dr. J. Ferguson, county M.O.H., Surrey, Prof. W. M. Frazer, M.O.H., Liverpool, and Dr. E. R. Peirce, senior assistant M.O., Port of Liverpool, for the supply of material from smallpox patients.

SONNE DYSENTERY AND NON-SPECIFIC GASTRO-ENTERITIS IN A HOSPITAL

LAURENCE MARTIN
M.D. Camb., M.R.C.P.
PHYSICIAN TO ADDENBROOKE'S HOSPITAL, CAMBRIDGE

M. M. WILSON
M.B. Camb.
LATE BACTERIOLOGIST, EMERGENCY PUBLIC HEALTH LABORATORY SERVICE

AN epidemic of Sonne dysentery broke out among the nurses and domestic staff of a large general hospital and its war-time annexe in the second week of January, 1945. The main epidemic had abated by mid-March, but sporadic cases occurred during April and August. Intermingled with the Sonne-positive cases were others presenting a similar clinical picture from which neither *Bact. sonnei* nor other pathogenic organisms could be isolated despite repeated bacteriological examinations. The non-specific cases continued throughout the period January to mid-November and, although most numerous in January, when the Sonne epidemic was at its peak, occurred at an average rate of 2 a fortnight. In the first fortnight of November, however, 6 cases occurred when there were no cases of Sonne dysentery.

The purpose of this paper is to compare the clinical findings and epidemiology of the cases of Sonne dysentery with those of the non-specific gastro-enteritis and to consider the possible ætiology of the latter.

Material.—In the community of about 400 nurses and hospital domestics 49 attacks of Sonne dysentery were observed in 48 persons, and 45 attacks of non-specific gastro-enteritis in 38 persons. Eleven persons had both diseases or two attacks of one of them. Thus 4 had Sonne dysentery preceding the non-specific gastro-enteritis by intervals of 1–9 months, and 1 had an attack of non-specific gastro-enteritis before an attack of Sonne dysentery; 5 persons had two attacks of non-specific gastro-enteritis, and 1 had two attacks of Sonne dysentery.

LABORATORY FINDINGS

Fæces or rectal swabs from all cases were plated within a few hours on Leifson's desoxycholate citrate agar; some were also cultured on Wilson and Blair plates and in tetrathionate broth. Leifson plates were examined after 16–24 hours' incubation, and suspicious colonies were tested by slide-agglutination and picked off to sugar media. A presumptive report of *Bact. sonnei* could thus be given in most positive cases within 24 hours. Negative Leifson plates were then incubated for a further 24 hours and examined again for missed Sonne colonies. All Sonne organisms were confirmed by biochemical reactions and tube agglutinations.

Bact. sonnei was isolated from the first fæcal specimen or rectal swab in the great majority of positive cases. Frequent specimens (3 to 12 or more) were examined from the non-specific cases while symptoms persisted, but no organisms of the dysentery, food-poisoning, or enteric groups were found.

Agglutination Reactions.—Sera were taken from 5 Sonne-positive cases and 5 non-specific cases at intervals varying from a few days to several weeks after the onset of symptoms. None showed any agglutination of *Bact. sonnei* at a dilution of 1/20.

CLINICAL FINDINGS

Onset.—The onsets of both Sonne dysentery and the non-specific gastro-enteritis were abrupt; sudden diarrhœa and/or vomiting, often in the early hours of the morning, being the rule. A few cases of both diseases had a premonitory phase of malaise with headache, giddiness, colic, nausea, or fever before the onset of diarrhœa or vomiting:

Mode of onset	*Sonne-positive attacks*	*Non-specific attacks*
Premonitory malaise ..	12	6
Diarrhœa	29	23
Vomiting	1	8
Diarrhœa and vomiting ..	4	8
Asymptomatic carriers ..	3	..
Total ..	49	45

The occurrence of initial pyrexia could not be correlated with either disease or with any particular mode of onset. Thus, in 18 of the 46 Sonne attacks (excluding the 3 asymptomatic carriers) and in 23 of the 45 non-specific attacks the patients were afebrile despite different modes of onset. No preceding or coincident upper respiratory infections were recorded in either disease. The degree of malaise and prostration was similar in both diseases but more severe in those patients who had high fever. It was impossible to predict from clinical observations whether a given patient would be Sonne-positive or not.

Stools.—All the Sonne-positive cases had frank diarrhœa, but some of the non-specific cases passed only one fluid motion daily. In 6 non-specific cases the patients did not have true diarrhœa at all after admission to hospital, though they had abdominal discomfort and rather loose motions.

The diarrhœa stools were fluid in both types of disease, and blood was never observed; mucus was often found in the Sonne-positive stools but only rarely in those from the non-specific cases. The number of stools averaged 7–8 during the first 48 hours of both diseases. The duration of diarrhœa could not be recorded in the Sonne-positive cases, because they were transferred to an infectious-diseases hospital as soon as the bacteriological diagnosis had been made. In the non-specific cases diarrhœa was usually of short duration and had almost always ceased by the fourth day. In 3 non-specific cases, however, diarrhœa continued for about 15 days, accompanied by a low intermittent fever, which never exceeded 99·4° F. In these cases the diarrhœa was uninfluenced by sulphaguanidine and sulphasuccidine, in contradistinction to the relief usually afforded by these drugs in Sonne dysentery.

Main Symptoms.—The main symptoms in the courses of 43 attacks of Sonne dysentery and of 36 attacks of non-specific gastro-enteritis are analysed as follows:

Symptom	*Sonne-positive (43 attacks)*	*Non-specific gastro-enteritis (36 attacks)*
Malaise	34	32
Nausea and/or vomiting	31	31
Headache	17	13
Vertigo or fainting	5	7
Tachycardia (90 +)	24	24
Pyrexia	24	22
Colic	30	29
Diarrhœa	43	30
Average no. of stools in first 48 hours	7–8	7–8

These numbers are smaller than the total number of attacks, because detailed information was not obtained in every instance.

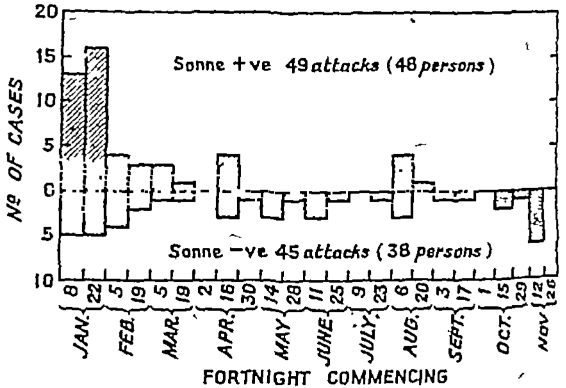
Fever.—The only clinical feature which, in retrospect, offered any distinction between the Sonne-positive and non-specific cases was the character of the pyrexia. The incidence of pyrexia was about 50% in cases of both diseases, but further analysis of the temperature charts showed a difference in character:

	Afebrile	*Low intermittent*	*High with quick fall*	*Total*
Sonne-positive ..	11	5	16	32
Non-specific ..	17	12	7	36

Charts of sufficient length were available in 32 attacks of Sonne dysentery and in 36 attacks of non-specific gastro-enteritis. Some patients were afebrile, others had a low intermittent fever—never exceeding 99·4° F, but which might last for 7–14 days—and a third group had an initial fever of 100–103° F which fell to normal during the first 48 hours and did not recur. We are satisfied that the occasional administration of sulphaguanidine did not affect the pyrexia during the first 48 hours.

Thus there was an initial high fever in 50% of the Sonne-positive cases but in only 20% of the non-specific cases. Half of the non-specific and a third of the Sonne-positive cases were afebrile, and the low intermittent fever was twice as common in the non-specific cases. Unfortunately this difference in character of the pyrexia is not sufficiently constant to be of use in differential diagnosis.

Course.—We cannot compare the duration of Sonne dysentery in our cases with that of the non-specific gastro-enteritis, because bacteriological cure was demanded for the former, whereas clinical cure was accepted for the latter. For the non-specific cases the average stay in hospital per attack was 7·4 days. In the 3 cases of continued non-specific diarrhœa mentioned above, stay in hospital was prolonged to 27, 27, and 20 days.



Fortnightly incidence of Sonne dysentery and non-specific gastro-enteritis.

To sum up the clinical aspect, the two diseases appeared, for all practical purposes, to be identical, and no obvious or constant means for their differentiation has emerged from this study.

EPIDEMIOLOGY

The fortnightly incidence of Sonne dysentery and non-specific gastro-enteritis is shown in the accompanying chart. The cases of Sonne dysentery occurred in three outbreaks. The first outbreak was due mainly to the presence of 6 infected persons in the kitchens of the hospital annexe: 3 had dysentery and 3 were asymptomatic carriers. After identification and removal of these persons the epidemic rapidly waned. Possibly a few nurses were infected in the wards by patients with Sonne dysentery. The two further minor outbreaks in April and August could not be traced to any source. Cases of Sonne dysentery were occurring in the district throughout the period of study, and nurses may have been infected outside the hospital.

The explosive character of the Sonne outbreaks was in contrast to the endemicity of non-specific gastro-enteritis, cases of which occurred in all but four of the fortnightly periods from January to mid-November. It is possible that more cases were detected in January and February than later owing to measures taken in these months to ensure reporting of any gastro-intestinal upsets. The occurrence of non-specific cases could not be correlated with any factors such as dormitory arrangements, wards in which the staff had worked, or infection by food or milk.

The nurses fed communally in dining-halls in the main hospital and in the annexe, and the domestics had imilar separate feeding arrangements. In the hospital oth nurses and domestics had separate bedrooms, but n the annexe they were housed in small dormitories. The Sonne dysentery cases were largely confined to the taff of the hospital annexe because of the infected kitchen personnel, but non-specific cases occurred equally in the main hospital and annexe.

DISCUSSION

Two forms of gastro-enteritis with indistinguishable clinical pictures were prevalent at the beginning of this study. One was an explosive outbreak of Sonne dysentery, emanating from infected kitchen staff, which quickly subsided, and the other was a gastro-enteritis of unknown cause which was endemic throughout the period under review and had not entirely ceased when the investigation closed.

Our non-specific cases did not exactly resemble hyperemesis hiemis—the winter vomiting disease—epidemics of which were described in America by Zahorsky (1929, 1940) as affecting children but rarely adults. Diarrhœa often occurred, but the stools were thin, light-coloured, and offensive, and not considered to be due to a true enteritis.

Nor did our cases correspond to the epidemic nausea and vomiting described in this country by Miller and Raven (1936), Gray (1939), and Bradley (1943), in which diarrhœa was always a minor symptom, pyrexia was infrequent, and the disease assumed an epidemic form. In our cases, although nausea and vomiting were frequent, diarrhœa was the most prominent symptom, and the cases occurred as a smouldering endemic. Epidemiologically our non-specific cases most resembled those reported by Brown et al. (1945), in which diarrhœa was the main symptom, and those recorded by Reimann et al. (1945a). The latter described "a mild widespread epidemic disease characterised by anorexia, malaise, diarrhœa, nausea, and vomiting" and noted its spread over several months without peaking. In later work Reimann et al. (1945b) brought forward evidence that a gastro-enteritis, attributed to a virus, could be transferred to human volunteers by nasal inhalations of (but not by swallowing) stool filtrates and filtered garglings from patients. This evidence certainly supported an airborne infection and favoured a filter-passing virus as the infective agent. The association of non-specific enteritis with Sonne dysentery was noted by Barnard (1945), who observed an outbreak of Sonne-negative diarrhœa, associated with vomiting, which lasted 3 or 4 days and followed a wave of Sonne dysentery.

We offer the following considerations about the nature of our cases of non-specific gastro-enteritis:

(1) The least unlikely possibility is that they were due to a virus, because the bacteriological investigations practically excluded their being due to infection with *Bact. sonnei* or other organism known to cause enteritis.

(2) The clinical features differed from those recorded in hyperemesis hiemis and in epidemic nausea and vomiting, because diarrhœa was the most prominent symptom.

(3) Their endemicity excluded mass infection of food and metallic poisoning, and suggested a spread by contact. Our observations provided no evidence to show whether transmission was effected by droplets or from fæces. It seems probable that carriers were present in the community but, because no bacterial agent could be incriminated, they could not be identified.

SUMMARY

The coincident occurrence of epidemic Sonne dysentery and endemic gastro-enteritis of unknown origin among nurses and domestics in a large hospital is described.

The salient features of the non-specific gastro-enteritis were its sparse but widespread distribution in the community, its smouldering character, and its close clinical similarity to Sonne dysentery.

It appeared to differ from "epidemic nausea and vomiting" and from "the winter vomiting disease" in having diarrhœa as its salient feature.

Its ætiology is discussed.

DIAGNOSIS OF EPILEPSY IN SERVICE CASES

T. B. S. DICK
M.B. Manc., M.R.C.P.
MAJOR R.A.M.C.
From an E.M.S. Neurological Unit

ONE of the most difficult problems of war medicine is to decide the nature of alleged epileptic attacks in serving soldiers. Accurate and rapid diagnosis is desirable for three reasons. First, since the Army authorities have laid down that virtually all epileptics should be discharged from the Service, the time and money spent in training a man will be entirely wasted if he later proves to have epilepsy. Secondly, it is clearly unfair to discharge a man to civil life with the label of epilepsy, and the stigma that this entails, without definite proof that the diagnosis is correct. Thirdly, the fact that there may be a conscious or subconscious desire to evade service must always be borne in mind.

Since 1941 nearly 500 cases of major epilepsy or suspected major epilepsy have been admitted to the Medical Neurological Unit at Winwick. The cases under consideration in this paper were those in which the diagnosis depended on an unsubstantiated history, there being no abnormal physical signs, no reliable accounts of attacks, and no evidence of trauma, tumour, syphilis, or cysticercosis.

In the first 164 cases of this group each case was provisionally diagnosed on the history alone as definite, probable, or improbable epilepsy.

ELECTRO-ENCEPHALOGRAM

The next procedure was to obtain an electro-encephalogram (E.E.G.). This was taken and interpreted by Mrs. E. M. Stewart-Gibb and Mr. Michael Saunders in the department of electro-encephalography at Manchester Royal Infirmary. The criteria of abnormality used in assessing these tracings were those laid down by the British E.E.G. Society. Except in a very few of the early cases all the patients were fasting, and all without exception were hyperventilated; none was on any form of therapy.

The E.E.G. tracings were assessed and placed in one of four groups: (1) "negative," being within normal limits; (2) "non-specific," showing a non-specific abnormality of rhythm of a type seen in a tenth of the normal population and in a higher proportion of neurotics and psychopaths, as well as in other neurological conditions; and (3) "very suggestive," presenting paroxysmal rhythms suggestive of epilepsy.

No tracings could be included in the fourth group—i.e., none showed the classical spike and wave or variant which is regarded as pathognomonic of epilepsy.

WATER PITRESSIN TEST

A water pitressin test was next performed on each case. McQuarrie and Peeler (1931), Jacobsen (1934), and others have shown that typical major epileptic seizures can be produced in many epileptic subjects by inducing a positive water balance in the body for a comparatively short period. The most rapid and effective way of attaining this positive water balance is by utilising the antidiuretic action of pitressin. In performing the test the method we adopted was substantially the same as that used by Clegg and Thorpe (1935), $^1/_2$ pint of water being given every two hours, and an injection of pitressin 0·25 c.cm. (5 units) followed by 0·5 c.cm. (10 units) every four hours, for forty hours. With the production of a major epileptic fit by this means the patient was regarded as having epilepsy. This test is not wholly devoid of unpleasant effects, and a small proportion of men refused to complete it, or even to undergo it at all.

McQuarrie and Peeler (1931), Clegg and Thorpe (1935), and others have done a control séries of water pitressin tests on normal people. In no case was a fit produced in a non-epileptic. Garland et al. (1943) state that they have been unable to find in the literature any record of a positive water pitressin test in a person not subject to epilepsy.

RESULTS

The total number of cases assessed was 164. In 142 the water pitressin test was completed. In 22 cases this test was not completed, for reasons other than the occurrence of an epileptic fit.

From a *clinical examination* 58 patients were considered to be definitely epileptic, 48 probably epileptic, and 58 improbably epileptic.

The *water pitressin test* gave 37 positive results and 83 negative, the remainder not being completed, often because of vomiting or severe headache.

"Very suggestive" E.E.G. numbered 8.

Though 250 cases were investigated in this way, the results of only the first 164 have been used in this paper, as it has not yet been possible to follow up the rest.

The *age* of the patients in this group is fairly evenly spread between 18 and 45. There appeared to be no correlation between the E.E.G. findings or the water pitressin findings and the age of the patient.

It should be emphasised once again that, in grouping the cases as "definitely epileptic," "probably epileptic," and "improbably epileptic," the diagnosis was made merely on the history and the general impression of the case from a clinical point of view. The rest of the investigation had not been carried out, and the diagnosis was merely provisional.

TABLE I—DETAILED RESULTS IN 164 CASES

Clinical diagnosis	Water pitressin test	E.E.G.	No. of cases
Definitely epilepsy	Positive	Negative	18
		Non-specific	7
		Very suggestive	2
	Negative	Negative	18
		Non-specific	11
		Very suggestive	2
Probably epilepsy	Positive	Negative	6
		Non-specific	1
		Very suggestive	1
	Negative	Negative	31
		Non-specific	7
		Very suggestive	2
Improbably epilepsy	Positive	Negative	0
		Non-specific	1
		Very suggestive	1
	Negative	Negative	46
		Non-specific	10
		Very suggestive	0

The detailed results are given in table I. There were 18 cases of clinical "definitely epilepsy" which had a positive water pitressin test and yet a normal E.E.G. On the other hand, there were in this group 2 "very suggestive" E.E.G. associated with a negative water pitressin test. Of the 2 "improbably epilepsy" cases with a positive water pitressin test, 1 had a "very suggestive" E.E.G. There is no reason to believe that a positive water pitressin test was obtained in a non-epileptic in either of these cases; the provisional diagno in both of them had been hysteria.

TABLE II—FOLLOW-UP RESULTS ON 164 CASES

Clinical diagnosis	No. of cases	Epilepsy confirmed	Total in which either E.E.G. or water pitressin or both were positive	Total still serving
Definitely epilepsy	58	51 (50*)	29 {W.P. .. 27 E.E.G. .. 4	7
Probably epilepsy	48	16 (12*)	10 {W.P. .. 8 E.E.G. .. 3	21
Improbably epilepsy	58	5 (3*)	2 {W.P. .. 2 E.E.G. .. 1	41

* Confirmed in hospital.

The *comparative results* were as follows:

Clinical diagnosis "definitely epilepsy" (58 *cases*)

Water pitressin test positive in	47%
E.E.G. very suggestive in	7%
E.E.G. non-specific in	31%

(6 water pitressin tests unfinished, patients refusing to continue

Clinical diagnosis "probably epilepsy" (48 *cases*)

Water pitressin test positive in	17%
E.E.G. very suggestive in	6%
E.E.G. non-specific in	17%

(5 water pitressin tests not completed, patients refusing to continue

Clinical diagnosis "improbably epilepsy" (58 *cases*)

Water pitressin test positive in	3%
E.E.G. very suggestive in	2%
E.E.G. non-specific in	19%

(11 water pitressin tests not completed, patients refusing to continue

The first 164 cases were followed up at least six month after the patient had left hospital. Confirmation o *a diagnosis of epilepsy means that a fit was* observe by a reliable witness, or the patient was subsequentl discharged from the Army as an epileptic by some othe neurological unit. The results are given in table II.

DISCUSSION

On the basis of these results, the water pitressin tes appears to be of more value than the E.E.G., and th *clinical evaluation of the patient* more important tha either of these tests in reaching a rapid and accurat diagnosis. It must be remembered, however, that a E.E.G. was obtained only once in each case. No doub if several tracings had been taken in each case, more woul have shown patterns suggesting epilepsy, but unfortunately this was impracticable. It should be remembere that those who interpreted the E.E.G. knew little of th clinical assessment beyond having a summary of th case-history. It has been suggested that more coul have been made of the interpretation of these tracing had a person skilled in both the clinical aspects and i electro-encephalography been in charge of the case though it is only fair to state that the electro-encephalographers concerned kept rigidly to the criteria laid dow by the British E.E.G. Society. Whether or not suc criticisms are valid, there is no doubt that the E.E.G. i often used merely as an *isolated test, and that* th limitations of this procedure are not perhaps wholl appreciated.

If the E.E.G. was of a non-specific type, *it was* considered by *the clinicians to be of* little or no value i assessing the diagnosis. Interseizure abnormaliti are often non-specific and of a type seen in at least 10% of the normal population (Gibbs et al. 1943). An eve higher proportion of neurotics (Williams 1941) an psychopaths (Hill and Watterston 1942) show simila abnormalities. Williams (1944) has sought to show tha episodic outbursts in these non-specific patterns are of considerable significance and strongly indicate epilepsy. Episodic outbursts were not accepted in this series as confirmatory evidence, but episodic outbursts of abnormal activity not amounting to larval attacks were accepted.

Gibbs et al. (1943) state that, in their experience, 42% of tracings were of little or no value in confirming a diagnosis of epilepsy.

Often the only confirmatory evidence of epilepsy was a non-specific pattern in the E.E.G. Bearing in mind what has already been said about the occurrence of these tracings in the normal population, in neurotics, and in psychopaths I feel that to know that a man has a non-specific dysrhythmia of this type is of little value in weighting the scales in favour of a diagnosis of epilepsy. But it must be admitted that, if the views put forward by Williams (1944) are accepted as correct, so-called non-specific abnormalities may now be of considerably more diagnostic value.

According to Finley and Dynes (1942), Jasper (1941), Hill (1944), and others tracings strongly suggesting epilepsy were found not uncommonly in conditions regarded as non-epileptic. It seems reasonable to regard such a tracing as strong confirmatory evidence of this diagnosis if the history also supports it; but when there is considerable clinical doubt about the exact diagnosis, even the finding of such a tracing should make one hesitate before discharging a man with the stigma of epilepsy.

I have found that a considerable number of medical officers seem to assume that all that is necessary to confirm or exclude a diagnosis of epilepsy is one E.E.G. This unfortunate tendency to substitute an E.E.G. report for a careful history and an examination is entirely unwarranted.

My view is that the E.E.G. used as a diagnostic aid as I have used it, and as I believe it is quite widely used by others, has only a limited value in the diagnosis of major epilepsy, and is less useful in this respect than is the water pitressin test. I believe that a careful clinical assessment is a more reliable means of reaching a correct diagnosis than is either the water pitressin test or the E.E.G., used either alone or together.

SUMMARY

In 164 cases of suspected epilepsy a routine investigation has been carried out, a provisional diagnosis being made in each case on the history alone Electro-encephalography and a water pitressin test were later performed on each case. A follow-up has been made, at least six months after the patient had left hospital, to reach a final and exact diagnosis if possible.

As a result of this investigation it appears that clinical evaluation of the case is the most reliable single factor in reaching an accurate diagnosis of major epilepsy; the water pitressin and the E.E.G. are both important as ancillary aids to this end, the water pitressin being the more useful of the two.

I have to thank Dr. Fergus R. Ferguson for arranging the encephalographic investigation of these patients; Drs. Fergus R. Ferguson, Gordon Holmes, and Joly Dixon for their help and advice in the preparation of this paper; and Dr. Michael Saunders and Mrs. E. M Stewart-Gibb for their coöperation in interpreting the E.E.G.

THERAPEUTIC USES OF KHELLIN

METHOD OF STANDARDISATION

MEDICAL STUDENT, HARVARD UNIVERSITY, U.S.A.

From the Faculty of Medicine, Fuad I University, Cairo

EXTRACTS of seeds of *Ammi visnaga* Lam. (Arabic khella), an umbelliferous plant growing wild in the Eastern Mediterranean regions, have been used by the local population since ancient times as an anti-spasmodic in renal colic and ureteral spasm.

Chemical analyses made in Cairo and Vienna have shown the active principle to be a di-methoxy-methyl-furano-chromone and thus to belong to the same group as coumarines and possibly flavones. Some workers call it visammin. but we prefer to use the original name khellin.

Khellin causes a conspicuous and long relaxation of all the visceral smooth muscle—the intestines, uterus, bile-ducts, bronchi, and especially ureters. In 1934 preparations of *Ammi visnaga*, in the form of the 1 in 10 tincture and the 1 in 40 decoction, were introduced into the Egyptian Pharmacopœia and recommended as an antispasmodic in renal colic.

ANGINA

In 1945 a fresh interest in khellin arose as the result of the discovery that it acts as an extremely potent coronary vasodilator which, in doses used, has no effect on the general blood-pressure and does not increase the oxygen requirements of the heart (Anrep and Misrahy 1945). This action of khellin lasts many hours. Khellin has now been tried in over 150 cases of angina. With single or repeated doses of 100 mg. for intramuscular injections, or 50–100 mg. by mouth, three times daily, the results were extremely encouraging. Some of our early observations have already been published (Kenawy and Barsoum 1945).

BRONCHIAL ASTHMA

In view of the fact that khellin has been shown experimentally to dilate the respiratory passages (Samaan 1932), it has also been tried in severe bronchial asthma. A complete and prolonged relief was obtained in 41 out of 45 cases after a single intramuscular injection of 200–300 mg. In 3 cases the relief was obtained after repeating the injection after an hour. In 1 case relief was not obtained; this case was complicated by bilateral pulmonary tuberculosis, double phrenic evulsion. and thoracoplasty. Complete relief is given 5–15 min. after the injection and usually lasts about 24 hours. Repeated daily administrations of khellin by injection or by mouth conspicuously reduce the number and severity of the attacks. In obstinate cases of severe status asthmaticus a second and sometimes a third dose has to be given at intervals of one or two hours to produce relief.

The action of khellin in bronchial asthma is not so prompt as that of adrenaline or of ephedrine. but it is more lasting. and, since it has no effect on the general blood-pressure, it can be safely administered even in hypertensive patients. Spirometric records made in asthmatic patients show that under the influence of khellin their vital capacity increases by 600–1000 c.cm., and that the speed of expiration becomes appreciably faster. Khellin relieved attacks in some cases resistant to adrenaline or to aminophylline. It is also safer than aminophylline to administer. Deaths due to aminophylline have been recorded.

In the doses recommended above khellin is not toxic. The only fairly constant effect of its administration was a general sensation of warmth without actual flushing. One patient complained of vertigo and slight nausea which, however, soon disappeared. Control injections free from khellin were occasionally given to our patients to exclude any psychological effect. No relief was ever obtained with these injections. We wish to emphasise that the dose of khellin suitable for the asthmatic is much greater than that used for angina.

STANDARDISATION

Since the publication of our observations a considerable number of preparations of *Ammi visnaga* are being offered to the public without proper control or standardisation. We wish to issue a warning that crude extracts of *Ammi visnaga* may cause undesirable effects, especially when used for intramuscular injections in concentrated solutions. In animals such extracts may cause long-continued oliguria. Taken by mouth crude extracts and decoctions often cause severe gastric irritation and nausea, and sometimes diarrhœa. Therefore all preparations of *Ammi visnaga* to be used by mouth or by injection should be freed from injurious impurities, and the final concentration of the active principle (khellin) should be standardised. Extracts for oral or intramuscular administration should contain not less than 50 mg. per c.cm.

Fahmy and El Keiy (1931) discovered that khellin in contact with solid $NaOH$ gave a characteristic pink colour. No other known extract in therapeutic use gives this reaction. Standardisation by the use of this reaction requires a progressive dilution of the extract until no more coloration is obtained with $NaOH$. Besides being rather laborious, this method entirely depends on the subjective factor of determining something which just fails to appear. In our experience the method gave, in duplicate determinations by two different observers, errors as high as 100%. We were therefore obliged to discard the method in its original form and to adopt the following modification, which proved to be satisfactory for rapid standardisation of pharmaceutical preparations containing the active principle.

Method.—A standard stock solution is prepared by dissolving 25 mg. of chemically pure khellin (melting point 154° C) in 100 c.cm. of distilled water. This solution keeps without deterioration for several months. For the standardisation, five flat-bottomed sampling-tubes, labelled from 1 to 5 and containing 5 c.cm. each of a saturated solution of KOH, are prepared: 0·05, 0·10, 0·15, 0·20, and 0·25 c.cm. of the stock solution of khellin are then added to the tubes in ascending order from no. 1 to no. 5. After a few minutes the characteristic pink colour of different intensities develops in the tubes. The coloration reaches a maximum in about 10 min. and remains unchanged for several hours, after which it gradually fades. The amount of khellin in each tube was thus 12·5, 25·0, 37·5, 50·0, and 62·5 µg.

1 c.cm. of the extract to be standardised is diluted with 200 c.cm. of water, and 0·20 c.cm. of this dilution is added to a sixth tube also containing 5 c.cm. of saturated solution of KOH. The developed colour is then matched in a colorimeter or by naked eye against the set of the standard dilutions. The difference in the depth of colour of the standards is so obvious that it is easy to find an exact match or to place the colour of the unknown between two neighbouring standard dilutions. In this way a standardisation of an extract with an accuracy of about 6 mg. per c.cm. can be rapidly made. When the unknown matches tube no. 4 containing 50 µg. of khellin the extract is of the required strength of 50 mg. per c.cm. No greater accuracy is required for pharmaceutical preparations of *Ammi visnaga*. However, if greater precision is desired, new dilutions of the standard must be prepared, each of the tubes to contain 0·10, 0·11, 0·12 c.cm., &c., of the stock solution. The degree of dilution of the unknown must in this case also be increased.

ROYAL SOCIETY OF MEDICINE

Penicillin in Neurology

THE first session of a joint meeting of the section of neurology with the Société de Neurologie de Paris was held on April 15, with Dr. DOUGLAS MCALPINE, the president, in the chair.

SUPPURATIVE CONDITIONS OF THE BRAIN AND MENINGES

Sir HUGH CAIRNS said that with the early preparations of penicillin (50–100 units per mg.) it had been necessary to work out minimal effective doses; and these have to some extent survived, even though the present-day penicillin II, containing 1650 units per mg., is an almost pure crystalline preparation. Early successes were obtained with accessible infections such as pyæmia and septicæmia; later it was found that larger foci of infection, such as bacterial endocarditis and pyogenic meningitis with macroscopic areas of fibrino-purulent material, are less easily treated; foci flare up when the penicillin concentration falls below the bacteriostatic level. With gunshot wounds it is not enough to instil penicillin in the hope that infection will be quenched, all macroscopic areas of necrotic and infective material must be removed.

Penicillin in the cerebrospinal fluid (C.S.F.) must be assayed when a method of chemotherapy is being elaborated, or in the absence of expected improvement It may be given by the lumbar or cisternal route, or into the lateral ventricle; unless there is blockage it will spread freely. Normally, 12,000 units will maintain a bacteriostatic level for 24 hours; but occasionally, for example early in the treatment of pyogenic meningitis, this dose may be given every 12 hours. The upper limit of tolerance for the crystalline penicillin has not yet been worked out; but heavy doses of 50,000–100,000 units may cause severe meningeal reactions. Such large doses can do no good and may do harm; and there is never occasion to exceed 20,000 units in one day. Intrathecal penicillin, if continued for some weeks, causes depression of the ankle-jerks, suggesting damage to the cauda equina; but this change is reversible.

Normally, penicillin is given by the lumbar route, if there is a block (of which the most important sign is difficulty in obtaining C.S.F. by lumbar puncture), then the cisternal approach may be adopted; but with head retraction this may not be easy, and blocks sometimes occur above the cisterna magna, so that there should be no hesitation about injecting into the lateral ventricle.

For pachymeningitis and subdural abscess penicillin is given into the subdural space, from which it passes about as rapidly as from muscle; usually 8000–10,000 units are injected every four hours.

Penicillin given systemically does not pass in appreciable amounts into the C.S.F. Nevertheless, systemic penicillin has its value in pyogenic meningitis, for these reasons: (1) it helps to combat the primary focus and the septicæmia from the primary focus or a relapsing meningitis; (2) it helps to overcome infection of the cerebral blood-vessels; and (3) it is probable, though not certain, that penicillin can pass from the blood-stream into the perivascular spaces of the brain, and it may thus be valuable in acute pyogenic meningitis (which is more correctly a meningo-encephalitis), also in limiting the spread of brain abscess. Penicillin appears to pass freely from the blood-stream into the subdural space; though here further evidence is needed.

Crystalline penicillin II seems to be non-toxic when iven systemically; one patient has received 300 million nits without reaction. The sulphonamides should be iven along with penicillin; they are especially valuable hen intrathecal penicillin is stopped.

Until the diagnosis of meningitis is established bacteriologically treatment should be confined to systemic enicillin and sulphonamides. Intrathecal injections of enicillin should only exceptionally be given in general ractice, owing to the risks of aggravating the pressure ffects of an inconspicuous brain abscess and of ntroducing an insusceptible organism.

With cerebral abscess penicillin has made complete xtirpation the rule, except where it is due to a missile wound and in the rare deep-seated abscesses, which are better treated conservatively.

After all major neurosurgical operations a powder of penicillin and sulphamethazine has been used as a routine, with significant reduction in the incidence of postoperative infections.

In infections due to susceptible organisms results with penicillin are good so long as the concentration remains sufficient; precise planning of treatment is even more essential than with less powerful remedies.

MENINGITIS

Dr. **Honor Smith** described the treatment of a series of cases of pyogenic meningitis, mostly pneumococcal. Penicillin, made up in a solution of 2000 units per ml., was given intrathecally once or twice daily for at least five days, in doses of 8000–16,000 units. Though the other routes must be used where necessary, as with spinal block, the lumbar route is normally safe, convenient, and effective.

Sulphonamides are also given in full doses; sulphadiazine is the preparation of choice. Sulphonamides, by preventing or delaying the deposition of fibrino-pus, help to keep the pathways clear for the circulation of penicillin in the C.S.F. They should be given as soon as the diagnosis is made, to tide the patient over the interval before penicillin is begun; they also serve to cover the period in which intrathecal penicillin is withheld.

Penicillin is given not only intrathecally but also systemically, to control any septicæmia as well as to attack the primary focus; and it is now considered that operation on the ear, where this is the focus, should not be undertaken during the acute stage.

The most common complications are spinal block and relapse. The treatment for relapse is the same as that for the original attack, and the prognosis is good provided that the relapse is promptly recognised and energetically treated.

Of 50 unselected cases of pneumococcal meningitis, 11 died, 2 of causes other than meningitis: of the remaining 9, 4 were virtually moribund on admission. Thus delay in instituting treatment, due usually to delay in diagnosis, was the commonest cause of failure.

Treatment follows the same lines in streptococcal and staphylococcal meningitis. Intracranial abscess is a relatively common complication of streptococcal meningitis; and in the presence of an abscess it is essential to give penicillin by the ventricular route. With meningococcal meningitis penicillin is rarely required, except where the response to sulphonamides is disappointing, or where the patient shows signs of intolerance, is vomiting persistently, or is severely dehydrated.

NEUROSYPHILIS

Dr. C. C. **Worster-Drought** recalled that for early syphilis a "standard" course of penicillin was originally evolved; this consisted in altogether 2,400,000 units, given in doses of 40,000 units every four hours over 7½ days, and the relapse-rate averaged about 15%. Experience of penicillin in neurosyphilis is based mainly on this "standard" course. The present tendency is, however, towards larger total amounts—4–5 million units, given three-hourly in doses of 40,000 units. Penicillin should be given intramuscularly: there is little to commend intravenous administration: continuous administration calls for cumbersome apparatus, and even repeated single intravenous injections carry the risk of thrombophlebitis.

More recently a single daily dose of 300,000–500,000 units for 14 days has been reported as giving just as good results; and Dr. Worster-Drought has found 500,000 units daily for 14 days fairly effective against meningovascular syphilis. Further time must elapse, however, before the results can be finally assessed. In view of the relapses with penicillin alone, he has never abandoned arsenic and bismuth; there may possibly be a synergistic action between the two types of treatment.

In neurosyphilis, is it necessary for penicillin to pass the blood-brain barrier? Probably not, since the state of the C.S.F. improves in meningovascular infection treated with parenteral penicillin only; and the same is true of parenchymatous syphilis. Whether or not it passes the barrier, parenteral penicillin exerts a definite influence on the meninges and the central nervous system. Dr. Worster-Drought used to give penicillin intrathecally, but he now uses the intramuscular route, except in tabes with severe and frequent lightning pains. It is inadvisable to use the cisternal route. Though only slight and transient symptoms have been observed by him after the initial doses of penicillin, he now gives 4–6 injections of bismuth before starting penicillin, in view of the known risk of Herxheimer reactions.

With meningovascular syphilis penicillin produces a striking improvement both clinically and in the C.S.F., in which the Wassermann reaction may become negative in 2–4 months. It is doubtful whether neurosyphilis continues to improve beyond four months after the end of penicillin treatment. Further improvement with repeated courses is not conspicuous.

The blood Wassermann reaction, especially in the parenchymatous forms of neurosyphilis, is little affected by treatment with penicillin. Usually the blood reaction remains positive after the C.S.F. reaction has become negative: this is a strong argument for following up penicillin with the usual arsenic and bismuth treatment.

In many cases of general paresis treated with penicillin alone the cells and protein of the C.S.F. become normal in four weeks and the Wassermann reaction negative in two months; but after a further six months the Wassermann reaction may again be positive, and consequently malaria therapy is still advisable: "I know of no case of general paresis which has maintained clinical improvement, with negative serological reactions, on penicillin treatment alone."

Again in tabes dorsalis, administration of penicillin leads to improvement in the C.S.F.; and if this is followed by protracted treatment with arsenic and bismuth the disease in most cases, and especially the early ones, can be arrested. Dr. Worster-Drought gives penicillin initially up to a total dosage of 4–5 million units, and then the usual courses of arsenic and bismuth up to three years. With severe lightning pains, slightly better results are obtained by intrathecal injection: 10,000 units are given in 10 ml. of saline daily for 10 days.

Penicillin has been said to be effective in the treatment of primary optic atrophy; but as this condition may progress slowly for five years before blindness ensues it is difficult so far to assess results: initial penicillin is advisable but full malaria treatment is essential.

Early asymptomatic neurosyphilis occurs as a meningovascular reaction in the secondary stage, when it is readily treatable: but the late form, occurring long after infection, often resists treatment and may terminate in general paresis. Penicillin is fully effective against the first type, and it is of value in treating the second, where the best method is first to give bismuth, which is followed by 4–5 million units of penicillin, and then by full malaria therapy.

Erb's paraplegia has unfortunately proved as resistant to penicillin as to other forms of treatment.

GENERAL PARALYSIS

Dr. W. D. **Nicol** reported, jointly with Dr. M. Whel experience of penicillin in 57 cases of neurosyphilis whom 42 were general paralytics. Of these, 14 treated with penicillin only, while the remainder re also malaria therapy. The patients given penicill were carefully selected: their physical condit poor, and the risk of malaria treatment high. T of penicillin was 300,000 units daily for 14 day of 4·2 mega units.

In the doses recommended above khellin is not toxic. The only fairly constant effect of its administration was a general sensation of warmth without actual flushing. One patient complained of vertigo and slight nausea which, however, soon disappeared. Control injections free from khellin were occasionally given to our patients to exclude any psychological effect. No relief was ever obtained with these injections. We wish to emphasise that the dose of khellin suitable for the asthmatic is much greater than that used for angina.

STANDARDISATION

Since the publication of our observations a considerable number of preparations of *Ammi visnaga* are being offered to the public without proper control or standardisation. We wish to issue a warning that crude extracts of *Ammi visnaga* may cause undesirable effects, especially when used for intramuscular injections in concentrated solutions. In animals such extracts may cause long-continued oliguria. Taken by mouth crude extracts and decoctions often cause severe gastric irritation and nausea, and sometimes diarrhœa. Therefore all preparations of *Ammi visnaga* to be used by mouth or by injection should be freed from injurious impurities, and the final concentration of the active principle (khellin) should be standardised. Extracts for oral or intramuscular administration should contain not less than 50 mg. per c.cm.

Fahmy and El Keiy (1931) discovered that khellin in contact with solid NaOH gave a characteristic pink colour. No other known extract in therapeutic use gives this reaction. Standardisation by the use of this reaction requires a progressive dilution of the extract until no more coloration is obtained with NaOH. Besides being rather laborious, this method entirely depends on the subjective factor of determining something which just fails to appear. In our experience the method gave, in duplicate determinations by two different observers, errors as high as 100%. We were therefore obliged to discard the method in its original form and to adopt the following modification, which proved to be satisfactory for rapid standardisation of pharmaceutical preparations containing the active principle.

Method.—A standard stock solution is prepared by dissolving 25 mg. of chemically pure khellin (melting point 154° C) in 100 c.cm. of distilled water. This solution keeps without deterioration for several months. For the standardisation, five flat-bottomed sampling-tubes, labelled from 1 to 5 and containing 5 c.cm. each of a saturated solution of KOH, are prepared: 0·05, 0·10, 0·15, 0·20, and 0·25 c.cm. of the stock solution of khellin are then added to the tubes in ascending order from no. 1 to no. 5. After a few minutes the characteristic pink colour of different intensities develops in the tubes. The coloration reaches a maximum in about 10 min. and remains unchanged for several hours, after which it gradually fades. The amount of khellin in each tube was thus 12·5, 25 0, 37·5, 50 0, and 62 5 µg.

1 c.cm. of the extract to be standardised is diluted with 200 c.cm. of water, and 0·20 c.cm. of this dilution is added to a sixth tube also containing 5 c.cm. of saturated solution of KOH. The developed colour is then matched in a colorimeter or by naked eye against the set of the standard dilutions. The difference in the depth of colour of the standards is so obvious that it is easy to find an exact match or to place the colour of the unknown between two neighbouring standard dilutions. In this way a standardisation of an extract with an accuracy of about 3 mg. per c.cm. can be rapidly made. When the unknown matches tube no. 4 containing 50 µg. of khellin the extract is of the required strength of 50 mg. per c.cm. No greater accuracy is required for pharmaceutical preparations of *Ammi visnaga*. However, if greater precision is desired, new dilutions of the standard must be prepared, each of the tubes to contain 0·1 0 11, 0·12 c.cm., &c., of the stock solution. The degree of dilution of the unknown must in this case also be increased.

Medical Societies

ROYAL SOCIETY OF MEDICINE

Penicillin in Neurology

THE first session of a joint meeting of the section of neurology with the Société de Neurologie de Paris was held on April 15, with Dr. DOUGLAS MCALPINE, the president, in the chair.

SUPPURATIVE CONDITIONS OF THE BRAIN AND MENINGES

Sir **HUGH CAIRNS** said that with the early preparations of penicillin (50–100 units per mg.) it had been necessary to work out minimal effective doses; and these have to some extent survived, even though the present-day penicillin II, containing 1650 units per mg., is an almost pure crystalline preparation. Early successes were obtained with accessible infections such as pyæmia and septicæmia; later it was found that larger foci of infection, such as bacterial endocarditis and pyogenic meningitis with macroscopic areas of fibrino-purulent material, are less easily treated; foci flare up when the penicillin concentration falls below the bacteriostatic level. With gunshot wounds it is not enough to instil penicillin in the hope that infection will be quenched; all macroscopic areas of necrotic and infective material must be removed.

Penicillin in the cerebrospinal fluid (C.S.F.) must be assayed when a method of chemotherapy is being elaborated, or in the absence of expected improvement. It may be given by the lumbar or cisternal route, or into the lateral ventricle; unless there is blockage it will spread freely. Normally, 12,000 units will maintain a bacteriostatic level for 24 hours; but occasionally, for example early in the treatment of pyogenic meningitis, this dose may be given every 12 hours. The upper limit of tolerance for the crystalline penicillin has not yet been worked out; but heavy doses of 50,000–100,000 units may cause severe meningeal reactions. Such large doses can do no good and may do harm; and there is never occasion to exceed 20,000 units in one day. Intrathecal penicillin, if continued for some weeks, causes depression of the ankle-jerks, suggesting damage to the cauda equina; but this change is reversible.

Normally, penicillin is given by the lumbar route; if there is a block (of which the most important sign is difficulty in obtaining C.S.F. by lumbar puncture), then the cisternal approach may be adopted; but with head retraction this may not be easy, and blocks sometimes occur above the cisterna magna, so that there should be no hesitation about injecting into the lateral ventricle.

For pachymeningitis and subdural abscess penicillin is given into the subdural space, from which it passes about as rapidly as from muscle; usually 8000–10,000 units are injected every four hours.

Penicillin given systemically does not pass in appreciable amounts into the C.S.F. Nevertheless, systemic penicillin has its value in pyogenic meningitis, for these reasons: (1) it helps to combat the primary focus and the septicæmia from the primary focus or a relapsing meningitis; (2) it helps to overcome infection of the cerebral blood-vessels; and (3) it is probable, though not certain, that penicillin can pass from the blood-stream into the perivascular spaces of the brain, and it may thus be valuable in acute pyogenic meningitis (which is more correctly a meningo-encephalitis), also in limiting the spread of brain abscess. Penicillin appears to pass freely from the blood-stream into the subdural space, though here further evidence is needed.

SURFACE ANAESTHESIA with NUPERCAINE

"Fortunately, Nupercaine is a complete substitute for cocaine."

Practitioner, 1936, 136, 509.

NUPERCAINE LOZENGES

each containing 1 mg., produce a prolonged anaesthesia of the mucous membranes of the mouth and throat, alleviate the discomfort of sore throat and allay post-tonsillectomy distress. *(Boxes of 15 and bottles of 100)*

NUPERCAINAL

a 1 per cent. ointment producing prolonged analgesia in chaps, herpes zoster, burns, sunburn, anal fissure, haemorrhoids, pruritus. *(Tubes of 1 oz.)*

NUPERCAINE SUPPOSITORIES

each containing 0.012 g., may be employed in the treatment of anal fissure and painful haemorrhoids or, post-operatively where a prolonged action is desired. *(Boxes of 5)*

NUPERCAINE 2% SOLUTION

for anaesthesia of the mucous membranes of the ear, mouth, throat and nose. May be employed topically in proctology. *(Bottles of 30 c.cm.)*

NUPERCAINE LUBRICANT

an efficient anaesthetic lubricant containing 10%, for use with tracheal tubes only, facilitates introduction and renders their presence more tolerable. *(Containers of 1 oz.)*

Samples are available for clinical trial,

* A copy of The Nupercaine Handbook, Part II, Ciba Handbook No. 2, second edition, a 32 page survey of the special advantages of Nupercaine for surface, infiltration and regional anaesthesia, will be sent free to members of the Medical Profession on request.

CIBA LABORATORIES LIMITED

HORSHAM · SUSSEX

Telephone: Horsham 1234 Telegrams: Cibalabs, Horsham

The interval since this series was treated has been too short for serological assessment. No Herxheimer reaction was observed in any case; results were best in patients who were mentally confused or physically in poor condition; and improvement during the actual course of treatment was remarkable, rendering some patients fit for subsequent malaria therapy. Penicillin failed, however, to save the lives of 1 patient with fulminating general paralysis and of 2 very advanced cases; so, in this respect, it is apparently no more successful than older forms of treatment. Penicillin will prove a useful adjunct to malaria, but the optimum dosage has yet to be determined.

Reviews of Books

Diseases of the Adrenals

LOUIS J. SOFFER, M.D., adjunct attending physician, Mount Sinai Hospital, New York. London: H. Kimpton. Pp. 304. 28*s.*

FOR some years the interest of physicians has been shifting from the attack to the defence—to the mechanism by which the constancy of the internal environment is maintained. Until recently knowledge of the adrenal glands was confined to that of Addison's disease, and little had been added to Addison's century-old description. Even now adrenal diseases may seem unimportant because they are so rare. Yet in the last 25 years a great deal has been learnt about the functions of the adrenals which closely concerns the practising physician and surgeon. Their place in the control of mineral metabolism and of water-balance would alone warrant this interest, but modern work has disclosed much about their relationship to shock, resistance to infection, and the response of the body to every form of insult.

This is the second book on the topic lately published, and it covers well the whole ground of adrenal physiology and pathology. Much smaller than Goldzieher's standard work, it bears comparison in accuracy and completeness, and by reason of its small size should perhaps prove even more useful to the general practitioner who tries to be up to date.

L'Électro-choc, et la psychophysiologie

JEAN DELAY, professeur agrégé à la Faculté de Médecine, Paris. Paris: Masson. Pp. 170. Frs. 230.

Professor Delay holds that since electrical convulsions benefit melancholia—and other mental syndromes—irrespective of the cause of the illness, they presumably act on the mechanism of the disorders and thus provide opportunity for further study of their pathology. The diencephalon, he believes, plays an important part in regulating instincts, mood, and consciousness: it is through action on the diencephalon that electrical convulsions bring about recovery from mental illness. The first part of the monograph deals with the relation of epilepsy to the diencephalon; Delay insists that the generalised classical convulsion (as opposed to the Jacksonian) is of diencephalic origin, and that the phenomena which have been observed to accompany the electrically induced fit are mainly such as excitation of the diencephalon could produce. The next section, on disorders of mood, similarly examines the controlling influence of the diencephalon, emphasising that it stands at the cross-roads of the extrapyramidal motor system and the endocrine system and is, by its connexions, peculiarly fitted to regulate the relation between emotion and intellect. In the final section, disorders of consciousness, which the author has previously investigated in his studies of memory, are likewise referred to the diencephalon: the obnubilation and the dreamlike condition found in twilight states are in Delay's experience remarkably responsive to electrical convulsive therapy. He reviews the evidence relating the diencephalon to sleep and waking, and concludes once more that in this group of confused cases it is through diencephalic excitation that the patient is aroused and restored to healthy vigilance. The extensive observations which the author and his collaborators have carried out on patients under convulsive treatment, and his skilful marshalling of the relevant data concerning the hypothalamus and its connexions and functions entitle his monograph to be regarded [illegible] valuable contribution, but it becomes evident repetition that he has stretched his thesis when the diencephalon is made accountable for much, it explains very little.

Skin Diseases in Children

(2nd ed.) GEORGE M. MACKEE, M.D., professor of dermatology and syphilology, New York Post-G Medical School, Columbia University, New York, ANTHONY C. CIPOLLARO, M.D., *associate in dermat* and syphilology at the school. London: Hamish Hamilton Medical Books. Pp. 448. 37*s.* 6*d.*

WHETHER or not a textbook on skin diseases confined to children is carrying specialisation too far is debatable: certainly many diseases cannot be presented in perspective. For example, it becomes irrelevant to say, that the commonest cause of rosacea is "the ingestion of stimulants, especially tea and alcohol." Dr. M remarks that children with acne feel inferior, humiliated, and sensitive; this is often true, but the usual reason is that the parents feel that a spotty-faced child is reflection on themselves—and do not conceal the feeling. The reader, coming to the statement that "faulty sex habits," whatever that may mean, "should be corrected" as part of the treatment of acne, will probably look back to make quite sure that the book really was published in 1946: actually no date of publication is given. This practice must be roundly condemned; no medical work of any sort should be published without a date. However, there is much valuable information in the book, and the sections on ringworm, congenital anomalies, and syphilis are particularly good.

Further Studies in Encephalography

E. GRAEME ROBERTSON, M.D., F.R.C.P., neurologist, Royal Melbourne Hospital and Children's Hospital, Melbourne. London: Macmillan. Pp. 103. 42*s.*

THIS short monograph is based on Dr. Graeme Robertson's investigations into the physics and radiology of encephalography. He observed that replacement of cerebrospinal fluid in the ventricles by gas introduced into the lumbar subarachnoid space was not achieved by flotation of the gas in the fluid alone. One of the factors responsible is elastic recoil of the brain, as a result of which gas can enter ventricular cavities which are at a lower level than the introduced gas. He therefore studied the passage of gas from the lumbar sac to the ventricles in living and dead subjects and in reconstructed models, and then applied his findings to altering the technique of radiology. Thus far his monograph is mainly of interest to the experts, but the illustration of his results will fascinate everyone. His radiographs of the pons and medulla, of the cerebellum, and of the third ventricle and its structures, including the infundibulum, are convincing and clearly valuable. Line diagrams with which he explains many of his plates might well have been extended to all.

The Irish Medical Directory and Hospital Year Book for 1946-47 (Dublin: Parkside Press, pp. 358, 15*s.* 6*d.*) fulfils the promise of its title and gives information about the doctors, hospitals, and public-health officers of all Ireland. It also contains an article on penicillin by Mr. Ian Fraser, surgeon to the Royal Victoria Hospital, Belfast, and a review of recent literature on the sulphonamides in surgery by Mr. William Doolin, editor of the *Irish Journal of Medical Science.*

Desirable Factors in Surgical Sutures, by Mr. E. J. Holder, B.PHARM. (obtainable from the author, 42, Lauder Road, Edinburgh, 9, pp. 56), deals chiefly with the effect of methods of preparation and of sterilisation on the durability and strength of catgut in the tissues. It seems careful work. The effects of chromic acid and iodine are clearly demonstrated. Like other investigators the author thinks that little is gained by using any but the thinnest strands of catgut. His conclusion that non-absorbable sutures cause considerable reaction in the tissues will be doubted by observers who have gone more carefully into the matter: the histological aspect must be taken into consideration as well as the naked-eye appearances on which alone he has relied. An interesting chapter on the chemical constitution of various types of catgut is included.

THE LANCET

LONDON: SATURDAY, APRIL 26, 1947

Food for Convalescence

EVERYONE is well aware that an acute illness, of whatever cause, will lead to loss of weight and strength; but the accompanying metabolic changes were not examined until recent years. It is now recognised that any acutely adverse circumstance, such as trauma, operation, hæmorrhage, or infection, is associated with an immediate outpouring of nitrogen in the urine, with the result that the patient passes into a phase of negative nitrogen balance. Though this tells us little more than we already knew, it shows that, partly at least, the weight-loss seen in acute illness is due to accelerated destruction of protein. From this little extra information new ideas have emerged which may improve the therapy of convalescence and lessen the risks of surgery.

As to the immediate origin of the excess of nitrogen which appears in urine after injury two views are held: (1) that it arises from an increase in katabolism of tissue protein or labile storage protein, and (2) that the tissues fail to utilise ingested protein and amino-acids. While both these sources may contribute to the total nitrogen loss, it is probable that destruction of endogenous protein is the more important. MADDEN and CLAY[1] have shown that a negative nitrogen balance develops in normally fed dogs in which a sterile abscess has been induced by the injection of turpentine, whereas in dogs whose labile protein stores have been depleted by a low protein intake such an abscess causes little or no increase in nitrogen loss. In both groups of animals the loss of protein can be made good by liberal protein feeding. CROFT and PETERS[2] suggest that the protein katabolic phase following trauma is a defensive response to injury, whereby protein is broken down in order to make available to the organism amino-acids essential for defence against the noxious agent at the height of its attack. In support of this hypothesis, they found that the addition of methionine to the diet of patients suffering from burns abolishes the negative nitrogen balance. LEVENSON et al.[3] have observed an early increase in the level of amino-acids in the plasma of burned patients, and attribute it to an increase in the rate of amino-acid production in the tissues. MAN et al.,[4] on the other hand, could see no correlation between the level of plasma amino-acids and the degree of nitrogen loss in patients after operation.

Whatever the fundamental cause and biological significance of the post-traumatic loss of protein, it is likely, if severe and long continued, to have certain harmful effects on the patient: apart from delaying recovery, it has been thought to diminish resistance to infection and to delay the healing of wounds. MAYCOCK et al.,[5] endeavouring to estimate the state of the circulation and cardiac output from the ballistocardiogram in patients before and after severe surgical operation, found that in patients who were kept in positive nitrogen balance by extra feeding the operation led to less disturbance of the circulation than in those who were losing protein: both objectively and subjectively, patients in whom protein destruction was compensated by extra feeding withstood surgery better than those in whom no special attempt was made to maintain nitrogen equilibrium. Similar findings are reported by KOOP et al.,[6] who draw attention, however, to the practical difficulty of getting the postoperative patient to take a high-protein diet. These workers tried to build up a high protein reserve by giving an excess of protein—if necessary as protein hydrolysate—for five days before operation, and they formed the impression that patients prepared for operation in this way did better than others

While the last word has not yet been said on protein metabolism in acute disease, and while we remain ignorant of the mechanisms involved in protein destruction, we cannot be certain that post-traumatic protein katabolism is in fact harmful enough to warrant inflicting unpalatable high-powered protein mixtures and digests on the sick. The work so far done has served, however, to focus attention on the dietetic aspect of hospital treatment, which has too often been overshadowed by the more dramatically urgent therapeutic measures which a given illness may necessitate. The organisation of hospital dietetics calls for a degree of integration and coordination of skills which is hard to achieve unless a positive effort is directed to a specific end. The work done in the Canadian army hospitals, which is reported elsewhere in this issue, illustrates the possible inadequacy of hospital diets, both for the severely ill and for the convalescent, and indicates the effort of organisation which is in fact necessary to ensure a daily intake of 2700–3500 calories with a protein ration of 100–170 grammes. In the hospitals of this country, no matter how complete the organisation for the dietetic care of patients may become, we have the additional difficulty of providing the dietetic machine with suitable material on which to work: as things now stand, it would be all but impossible to find a daily ration of 170 grammes of palatable protein for each patient who could be judged in need of it. Moreover, it can be difficult to induce convalescent patients to consume such diets, without recourse to force-feeding techniques. Again, it is one thing to see that protein is swallowed, but quite another to ensure that it is fully utilised; and for the invalid there is point in the Shakespearian toast "Now, Good Digestion wait on Appetite, and Health on both." None the less, the Canadian experience emphasises once more the deficiencies both in what we achieve and in what we attempt. Neither food shortages nor anything else excuse our hospitals from providing, to the best of their ability, the kind of food most likely to induce appetite and restore the patient's strength

CAPILLARY FRAGILITY

Rutin is a crystalline glycoside obtained from the leaves and flowers of buckwheat. Recent reports attribute to Rutin the property of reducing capillary fragility when this is abnormally raised.

In our research laboratories a limited quantity has been isolated from buckwheat grown in this country and is available in the form of tablets.

Rutin A & H is suggested for administration in *hæmorrhagic conditions* due to *increased capillary* fragility or permeability, especially when this condition is associated with hypertension, nutritional deficiency or toxic effects of drugs.

Literature and price on application.

Food for Convalescence

EVERYONE is well aware that an acute illness, of whatever cause, will lead to loss of weight and strength; but the accompanying metabolic changes were not examined until recent years. It is now recognised that any acutely adverse circumstance, such as trauma, operation, hæmorrhage, or infection, is associated with an immediate outpouring of nitrogen in the urine, with the result that the patient passes into a phase of negative nitrogen balance. Though this tells us little more than we already knew, it shows that, partly at least, the weight-loss seen in acute illness is due to accelerated destruction of protein. From this little extra information new ideas have emerged which may improve the therapy of convalescence and lessen the risks of surgery.

As to the immediate origin of the excess of nitrogen which appears in urine after injury two views are held: (1) that it arises from an increase in katabolism of tissue protein or labile storage protein, and (2) that the tissues fail to utilise ingested protein and amino-acids. While both these sources may contribute to the total nitrogen loss, it is probable that destruction of endogenous protein is the more important. MADDEN and CLAY [1] have shown that a negative nitrogen balance develops in normally fed dogs in which a sterile abscess has been induced by the injection of turpentine, whereas in dogs whose labile protein stores have been depleted by a low protein intake such an abscess causes little or no increase in nitrogen loss. In both groups of animals the loss of protein can be made good by liberal protein feeding. CROFT and PETERS [2] suggest that the protein katabolic phase following trauma is a defensive response to injury, whereby protein is broken down in order to make available to the organism amino-acids essential for defence against the noxious agent at the height of its attack. In support of this hypothesis, they found that the addition of methionine to the diet of patients suffering from burns abolishes the negative nitrogen balance. LEVENSON et al. [3] have observed an early increase in the level of amino-acids in the plasma of burned patients, and attribute it to an increase in the rate of amino-acid production in the tissues. MAN et al.,[4] on the other hand, could see no correlation between the level of plasma amino-acids and the degree of nitrogen loss in patients after operation.

Whatever the fundamental cause and biological significance of the post-traumatic loss of protein, it is likely, if severe and long continued, to have certain harmful effects on the patient: apart from delaying recovery, it has been thought to diminish resistance to infection and to delay the healing of wounds. MAYCOCK et al.,[5] endeavouring to estimate the state of the circulation and cardiac output from the ballisto cardiogram in patients before and after severe surgical operation, found that in patients who were kept in positive nitrogen balance by extra feeding the operation led to less disturbance of the circulation than in those who were losing protein: both objectively and subjectively, patients in whom protein destruction was compensated by extra feeding withstood surgery better than those in whom no special attempt was made to maintain nitrogen equilibrium. Similar findings are reported by KOOP et al.,[6] who draw attention, however, to the practical difficulty of getting the postoperative patient to take a high-protein diet. These workers tried to build up a high protein reserve by giving an excess of protein—if necessary as protein hydrolysate—for five days before operation, and they formed the impression that patients prepared for operation in this way did better than others.

While the last word has not yet been said on protein metabolism in acute disease, and while we remain ignorant of the mechanisms involved in protein destruction, we cannot be certain that post-traumatic protein katabolism is in fact harmful enough to warrant inflicting unpalatable high-powered protein mixtures and digests on the sick. The work so far done has served, however, to focus attention on the dietetic aspect of hospital treatment, which has too often been overshadowed by the more dramatically urgent therapeutic measures which a given illness may necessitate. The organisation of hospital dietetics calls for a degree of integration and coördination of skills which is hard to achieve unless a positive effort is directed to a specific end. The work done in the Canadian army hospitals, which is reported elsewhere in this issue, illustrates the possible inadequacy of hospital diets, both for the severely ill and for the convalescent, and indicates the effort of organisation which is in fact necessary to ensure a daily intake of 2700–3500 calories with a protein ration of 100–170 grammes. In the hospitals of this country, no matter how complete the organisation for the dietetic care of patients may become, we have the additional difficulty of providing the dietetic machine with suitable material on which to work: as things now stand, it would be all but impossible to find a daily ration of 170 grammes of palatable protein for each patient who could be judged in need of it. Moreover, it can be difficult to induce convalescent patients to consume such diets, without recourse to force-feeding techniques. Again, it is one thing to see that protein is swallowed, but quite another to ensure that it is fully utilised; and for the invalid there is point in the Shakespearian toast "Now, Good Digestion wait on Appetite, and Health on both." None the less, the Canadian experience emphasises once more the deficiencies both in what we achieve and in what we attempt. Neither food shortages nor anything else excuse our hospitals from providing, to the best of their ability, the kind of food most likely to induce appetite and restore the patient's strength.

Persistence of Smallpox Virus

IN former days, studies of the mode of spread of smallpox taught us much about the transmission of infectious disease in general. Such studies, made in the field, were chiefly observations on the natural course of events. At first, when smallpox was widespread, it was often difficult to discover how any particular person had acquired his infection; but when the incidence was reduced to a few sporadic cases, or to imported infections, the manner of spread became more frequently and more clearly evident. In this way we learnt that contagion, direct or indirect, was the ordinary means of transmission; and in outbreaks of variola minor in 1921 and 1925 J. J. BUTTERWORTH in Lancashire was able to find the source of infection of almost every patient. In major smallpox the striking distance seemed to be somewhat greater, and in some of the hæmorrhagic outbreaks there has been evidence of droplet infection. It became clear, too, that for a time the patient's body remains infective after death; in Hamilton, Ontario, for example, a number of people contracted the disease after attending the funeral of the mayor, who died from an unrecognised hæmorrhagic attack.

It was also fairly certain that smallpox infection could persist in the patient's bedding and clothing. This was shown by cases in disinfecting staffs handling fomites, and by outbreaks in laundries (as at Wallasey early this century) where it was found that ability to infect might even survive the process of washing. An even longer persistence of infection was assumed when smallpox broke out at Oldham, in mills where Egyptian cotton was spun, at a time when the disease was prevalent in Alexandria. The analogy of vaccinia virus, which resists dehydration by glycerin, led to a firm belief that the variola virus strongly resists drying. Actually, as long ago as the early 18th century, physicians in this country were familiar with a method of immunisation by dried crusts kept for the purpose by the Chinese—

> "who take the skins of some of the dried pustules which have fallen from the body, and put them into a porcelain bottle, stopping the mouth of it very closely with wax. When they have a mind to infect any one, they make up three or four of these skins (inserting between them one grain of musk) into a tent with cotton, which they put up the nostrils."[1]

Any doubts that may have remained about the viability of the virus will be finally dispelled by the laboratory experiments of Professor DOWNIE and Dr. DUMBELL which we publish this week. They find that virus from vesicle fluid will grow on the chorio-allantois of the chick after being kept in the dark for as long as 84 days: and even this is by no means the limit; for crusts from healing lesions, kept in the dark at room temperature, yielded virus after 417 days, and crusts kept in vacuo over calcium chloride were still infective after more than two years.

Evidently, therefore, unless they are properly disinfected, articles used by a smallpox patient may long remain capable of transmitting the disease. Indeed, in the light of DOWNIE and DUMBELL's findings, there is probably no further need to invoke aerial convection to explain the vagaries of smallpox spread. We now have an adequate explanation of recent cases in which smallpox has occurred in houses to which presents of leather goods, or the like, had been brought back from the East—the disease even being confined to the recipient of the present. Prudence, however, dictates that, before accepting such an explanation in any particular case all possible care should be taken to discover a human source of the infection who has been somehow overlooked.

Absorbable Hæmostatics

THE history of surgery is reflected in the development of the methods of hæmostasis. "The confidence gradually acquired from masterfulness in controlling hæmorrhage gives to the surgeon the calm which is so essential for clear thinking and orderly procedure at the operating-table."[1] It has been a long road from the pre-Hippocratic tenaculum to the modern artery forceps; and no less arduous a one from HEWSON's and JONES's classical experiments on the "coagulable lymph" of blood, dating from 1771, to our present understanding of the intricate biochemistry of hæmostasis.

Attempts to encourage clotting at the site of blood-vessel rupture have an extensive history. AMBROISE PARÉ dressed bleeding wounds with a mixture containing white of egg ("étoupe trempée dans une sorte de pâté faite de blanc d'œuf."[2]). PERTHES[3] applied defibrinated blood of the rabbit to the wound and injected it under the bleeding surface; BROCA[4] recommended local applications of human serum; others[5] favoured proteins, such as gelatin. These empirical techniques led up to the clearer conception of hæmostasis by locally applied absorbable agents which is developing today. Absorbable hæmostatics are intended for application to sites of hæmorrhage which cannot be readily controlled by a hæmostat and when the removal of mechanical pressure or a temporary plug may lead to recurrence of bleeding; when the hæmorrhage is arrested they are absorbed by the tissues. HARVEY CUSHING and VICTOR HORSLEY were the first to propose striated muscle for this purpose, and such "muscle-stamps" well illustrate the principles of an absorbable hæmostatic—they transmit pressure, contain clot-promoting substances, and are absorbed. They have been widely used in neurosurgery, but the risk of infection and the impossibility of sterilisation have limited their value. It was CUSHING also who pointed the way to the use of fibrin as an absorbable hæmostatic—". . . the fibrin from whipped blood might be so prepared that it could be immediately plastered on bleeding surfaces, just as cotton is now used, and thus obviate the necessity for any subsequent replacement."[6] There is little to add to this definition. An ideal absorbable hæmostatic must be as simple to use as cotton-wool or gauze; it must be absorbed at the right speed, so that neither replacement nor removal is necessary; it must be safe—i.e., sterilisable by recognised practical methods.

The late war stimulated many advances in this field. In close succession fibrin foam, oxidised cellulose, and gelatin sponge have been developed in America: calcium alginate in England. The American materials, used in conjunction with thrombin (and also without) have already proved their value. Experimentally they show much the same absorbability in tissue. Fibrin foam, the earliest material to reach the clinical stage, is absorbed from the liver, peritoneal cavity, abdominal wall, kidney and lung in about five weeks[7]; in animals only a minimal amount of fibrous tissue is found at the site of implantation after this time. Soon after the foam has been applied polymorphs invade the implant area, and a tissue reaction characterised by many mononuclears and a few lymphocytes is elicited. About three weeks after implantation there is a well-marked giant-cell reaction. But the tissue reaction produced is far less than to a "muscle-stamp" of the same size. The safety and efficacy of fibrin foam were established by extensive trials in neurosurgery, and experience gained in 240 general surgical operations, including some on hæmophiliacs, corroborated the earlier results at Harvard. Perhaps the sole drawback to fibrin foam is the slightly complicated method of use, involving the "mixing in" of freshly prepared thrombin; sterilisation also requires a special procedure.

Oxidised cellulose (oxycellulose), developed by **Frantz** and her co-workers at Columbia University, New York, is prepared as a gauze and is easier to use than fibrin foam. The tissue reactions to the two are much the same. There is said to be an actual chemical combination between oxidised cellulose and hæmoglobin, and it seems best to apply it without thrombin. In staunching bleeding a sticky gelatinous mass forms, not a clot; this can be lifted away twenty-four hours later leaving a thin film of fluid between the material and the raw surface, without restarting the bleeding. Whereas fibrin foam can be applied in the presence of penicillin, oxidised cellulose inactivates the drug and is thus contra-indicated where penicillin is essential; it apparently delays bone repair and its sterilisation has to be effected by chemical methods. Clinical reports on well over 100 cases[8] have proved it to be efficacious in a variety of operative procedures. The third substance developed in the United States—gelatin sponge ('Gelfoam') is whipped or foamed gelatin. This is sterilisable by dry heat (autoclaving destroys its physical properties) and can be satisfactorily used with or without thrombin. It does not inactivate penicillin. **Jenkins** and **Clarke**[9] noted that there was sometimes a sharp inflammatory reaction to the sponge, which brought about its early liquefaction; where the early tissue response was slight the sponge became encapsulated by fibrous tissue and was subsequently removed by the phagocytosis of macrophages. After a clinical study in which gelatin sponge was used in 272 neurosurgical operations and fibrin foam in 115 similar cases, **Pilcher** and **Meacham**[10] preferred gelatin sponge, which was easier to apply; it can be cut with scissors and retains its tensile strength on wetting.

Hard on the heels of these American developments **Blaine** et al,[11] in England, have reported on yet another absorbable hæmostatic—calcium alginate—which is derived from Scottish seaweed and is increasingly utilised in British industry, to which must go the credit for its development. When sodium alginate solution reacts with a calcium salt coagulation immediately takes place, making it possible to prepare hæmostatic foams, filaments, cloth, gauze, wool, or a film resembling 'Cellophane' which can be prepared in situ. Calcium alginate can be autoclaved without serious loss of physical properties, and it can carry penicillin without inactivating it. Its versatility makes it easily adaptable for special purposes. Of the recently developed materials calcium alginate alone awaits clinical trial.

The absorption-rate of all these hæmostatics depends on their bulk and on the reaction of the tissue or organ in which they are placed. An experimental study of the effect of different pH levels in various sites of implantation might shed further light on absorption-rates; it would be of interest to establish graded absorption-rates best suited to diverse purposes. Apart from fibrin and thrombin, which play a direct part in blood-coagulation, they probably owe their hæmostatic effect to the great surface they offer to extravasated blood. Calcium alginate may also aid hæmostasis by enhancing prothrombin formation by releasing calcium.

Annotations

AN AMERICAN HOSPITAL SURVEY

The Michigan Hospital Survey,[1] undertaken as a pilot study of a single State, covers the whole range of hospital provision for urban and rural communities. While much of it goes over the same sort of ground as the recent hospital surveys in this country, the report does not always take the same line. For example, it recommends that the general hospital should not exceed 750 beds in size: "when an institution becomes too large, the administrative procedures of the service may become too impersonal and cumbersome, and this will be reflected in the quality of care given to the patient." As we said last week, we hope the regional boards will give due weight to this consideration when they come to set up their hospital management committees.

How many beds are needed in a given community? The Michigan surveyors reject the arbitrary method of assuming so many beds per thousand of the population, and have attempted what seems to be an entirely fresh approach to the problem. "It is now thought," they say, "that the number of general hospital beds for any community is directly proportioned to the crude birth and death rates." Hospital and vital statistics show that the public use about 250 days of general hospital care for each death and correlated sickness in a general hospital, and the number of beds needed can be deduced from an estimate of the number of deaths that will take place in hospital. The proportion of people dying in hospital is nearly 38% in Michigan, and as high as 50% in some other States. "We should strive," the survey suggests, "for an average level of hospitalisation whereby at least 50% of all deaths and correlated sickness occur in general hospitals, whilst some 8%–10% would occur in other types of hospitals and institutions." The surveyors evidently believe that, used with discretion, their "bed-death ratio" represents a real advance on

[1] The survey was undertaken by the staff of the American Hospital Association's Commission on Hospital Care, with Dr. A. C. Bachmeyer as director of study. It was financed by the W. K. Kellogg Foundation, of Battle Creek, Michigan, which publishes the report.

existing methods of estimating needs, and it would be useful to the Ministry of Health if statisticians over here would work out its possible application in this country. Bed-occupancy rates are also discussed, in relation to hospitals of different sizes and different degrees of segregation: "the smaller communities need more beds per thousand people because they must depend on smaller hospitals." Nothing, however, is said about costs, beyond a casual observation that "if hospitals could be constructed at $8000 per bed, approximately $90 million would be required to provide all the first class general hospital facilities that the State now needs." When, one may ask, is the curve of hospital provision going to level out, if not begin to fall?

This Michigan report emphasises, as our own hospital surveys can scarcely be said to have done, the educational aspect of nursing, and its recommendations for training schools resemble those lately made in these columns.[2] Hospitals which conduct schools of nursing should, it says, maintain separate budgets for the hospital nursing service and the nursing school, and "the value of services rendered by student nurses should be reflected in the accounts as a charge against the hospital, and a credit to the school." The school must have adequate financial support, which can be drawn from "endowment income, tuition and fees, taxation, and payment to the school by the associated hospitals for the nursing service rendered to the patients." An integrated system of hospitals would make it possible for the nurses' training schools to develop their curricula to the point where they could provide students with a varied experience of nursing in the hospitals, in the medical service centres, and in the field of public health.

ANTIBIOTICS IN BILIARY DISEASE

CHEMOTHERAPEUTIC drugs which were active against the coli-typhoid organisms and were excreted and concentrated in the bile would have considerable value as a substitute for or adjunct to surgery in cholangitis, cholecystitis, and empyema of the gall-bladder, and they might cure those chronic typhoid carriers in whom the gall-bladder has proved to be the reservoir of the organism. The sulphonamides, penicillin, and streptomycin are excreted in the bile of healthy men and animals, but it does not necessarily follow that these substances will be similarly excreted if the liver or the biliary tract is diseased or functioning poorly. Thus, Zaslow et al.[3] have shown that where there is clinical or laboratory evidence of liver disease and dysfunction, excretion of penicillin and streptomycin in the bile may be absent or reduced, whereas if the biliary tract is returning to normal function after surgical drainage these drugs are excreted in the bile. These American workers agree with Mr. E. G. Tuckwell, who reported his findings at the Royal Society of Medicine on March 5, in finding that, with normal liver function, the level of penicillin is usually higher in the bile than that in the blood within the first 2 hours after parenteral injection, whereas streptomycin is usually less concentrated in bile than in blood and reaches its peak rather later than does penicillin. Indeed, Zaslow et al. suggest that a biliary level below 0·5 unit of penicillin per c.cm. after an intramuscular dose of 15,000 units, or below 1·5 units of streptomycin after the injection of 100,000 units, is an indication of impaired liver function.

These drugs may reach the gall-bladder bile either by aspiration through the cystic duct or by passage through the blood-vessels in the wall of the gall-bladder. Normally, as Tuckwell showed, penicillin is present in the gall-bladder bile and may reach higher levels there than in the hepatic ducts, probably through concentration of the bile by fluid absorption. However, when the cysti duct is obstructed, penicillin is not found in gall-bladde bile, showing that the drug enters the gall-bladde through the biliary ducts and not through the bloodstream. Thus, in a group of 25 patients who were t undergo cholecystectomy, Zaslow et al.[4] found n penicillin in the gall-bladder of 8 cases; in 7 of thes the cystic duct was obstructed by stones while in th eighth no penicillin was being excreted in the hepati ducts. Unfortunately, cholecystography, using th iodophthalein dyes, may not indicate correctly whethe the cystic duct is patent. In the group in which penicilli was present in the gall-bladder and 4–14 hours elapsed between administration of the drug and cholecystectomy, the findings showed that the drug was neither much concentrated nor rapidly absorbed or excreted. The same applied to streptomycin.

The prospect of cure by chemotherapy in acute or chronic infections of the biliary tract is therefore not very bright, since neither penicillin nor streptomycin, nor presumably sulphonamides, will be excreted in the bile in significant amount if there is intrahepatic or extrahepatic biliary disease. Moreover, concentration in the gall-bladder will depend on patency of the cystic duct, which cannot be relied on in the type of patients among whom chronic typhoid carriers are usually found.

BLOOD-PRESSURE AND AGE

A YEAR or two ago we suggested that "few would now rely on the old dictum that the normal systolic blood-pressure, expressed in mm. Hg equals 100 plus the patient's age expressed in years."[5] Now we have American workers expressing the opinion that "the old maxim '100 plus the age' may actually be a fair index of normal systolic blood-pressure."[6] This conclusion is based on a series of 5331 white men between the ages of 40 and 95, some of whom have previously been reported on.[7, 8]

Analysis of the average systolic and diastolic pressures showed that though both rise with increasing age, the rise in the former is much greater. Thus the average systolic pressure increased from 133·3 mm. Hg in the 40–44 age-group to 164 in the 85–95 group, while the corresponding figures for the diastolic pressure were 84·8 and 90. This change with age is shown even more clearly by a comparison of the proportion in each age-group with "normal" blood-pressure (145/95 or less), systolic hypertension (150 or more /95 or less), and diastolic hypertension (diastolic pressure of 96 or more). The percentage with "normal" blood-pressure fell progressively with age from 87·2 at 40–44 to 27·8 at 85–95, while there was an equally striking increase in the incidence of systolic hypertension—from 4·2% to 45·2%. The rise in incidence of diastolic hypertension was less marked—from 8·5% at 40–44 to 27% at 85–95. The trends of "normal" systolic and diastolic pressures showed a progressive rise: the systolic rose from 129·6 at 40–49 to 134·1 at 80–95, the corresponding diastolic figures being 80·9 and 74·5. With advancing years there was no significant change in the incidence of pressures of 120/80 or less, but there was a biggish rise in the frequency of systolic pressures between 140 and 149 (from 18·6% at 40–49 to 40·9% at 80–95). Diastolic pressures below 70 rose from 3·6% at 40–49 to 21·2% at 80–95. The fact that diastolic pressure tended to fall rather than rise as age increased is adduced in answer to any suggestion that the series is vitiated by the inclusion of people with latent or potential hypertension.

If, as these observations indicate, the systolic pressure rises with age, what is the mechanism? Two factors

are probably involved—a neurogenic and a vascular. Russek and his associates [9, 10] have already shown that the reactibility of the blood-pressure, as judged by the cold pressor test, increases with age; and Dock [11] believes that this increase is related to trophic loss of neurones with ageing. The vascular factor, however, is probably more important, consisting of a progressive diminution of elasticity of the aorta and its larger branches. This change results in a higher systolic and lower diastolic pressure, whereas the neurogenic factor raises both systolic and diastolic. In other words, the neurogenic and vascular factors have a summating effect on the systolic pressure, but opposing effects on the diastolic pressure.

Two practical implications emerge from this study: (1) the upper limit of normality for the systolic pressure in the elderly must be accepted as considerably above 140 mm. Hg; and (2) in identifying essential hypertension emphasis must be laid on the diastolic rather than the systolic pressure. This latter view has been gaining ground in recent years; Hines,[12] for instance, suggested that only the diastolic pressure is of value in predicting the subsequent development of hypertension. It has also been generally accepted for many years that the prognosis in the elderly is much better with systolic hypertension than with diastolic hypertension. What is only now being elucidated is the "normal" blood-pressure for that increasingly large section of the community over the age of 50 years.

THE WHEELS TURN

THIRTEEN days at Geneva, from March 31 to April 12, were barely sufficient to dispatch the business of the third session of the Interim Commission of the World Health Organisation. The terminal scramble was partly due to the commission's failure to recognise that they had undertaken more than the secretariat could manage and partly to an inveterate tendency among some members to reopen questions already decided. Much good work, however, was done, and some important decisions taken in a most cordial atmosphere, to which the member from the U.S.S.R., Dr. C. A. Kolesnikov, was a notable contributor. As the chairman, Dr. A. Stampar, remarked in his closing speech, no serious differences of opinion were revealed and no voting was necessary. Of the 18 members 16 attended, Dr. I. Medved of the Ukraine and Dr. J. Togba of Liberia being unavoidably absent—the former because of his recent elevation to the post of minister of health. Sir Wilson Jameson was present during the first week of the session. Observers attended from the United Nations, F.A.O., the International Children's Fund, the International Refugee Organisation, the International Civil Aviation Organisation, the Paris Office, the Pan-American Sanitary Bureau, Unesco, and Unrra.

The most important task before the commission was to balance the budget, since the decisions taken at the second session last November [13] called for an excess of expenditure over income of some 300,000 dollars. By careful pruning this was achieved, even with the inclusion of some new items, except for a necessary reserve of 200,000 dollars, for which a further loan from the United Nations may be required. Among the new items an omission was repaired by providing for an expert committee on tuberculosis, and experts on child welfare and nutrition, venereal diseases, infant mortality, and influenza are to be appointed. The commission approved the allocations of funds for field services, derived from Unrra, according to the requests from countries for missions, fellowships, visiting lecturers, and medical literature, and also approved the agreements concluded with the governments of Greece and Ethiopia for field missions.

The commission did not see entirely eye to eye with the observer from Unesco, Mr. J. Needham, F.R.S., on the apparent encroachments of that body into the territory of health, but it was decided to set up a joint committee on the organisational level to define the boundaries. A joint committee on nutrition with F.A.O. will also be set up, to which the International Children's Fund may be conjoined. The negotiating subcommittee on relations with the Pan-American Sanitary Bureau reported considerable progress, which, as it failed to satisfy some members and went too far for others, was probably the best practicable mean.

Technical matters were chiefly dealt with by the committee on epidemiology and quarantine and by the new committee on priorities. Studies are to be undertaken by the secretariat on postvaccinal encephalitis, the "immune reaction" in vaccination, and immunisation against influenza. A meeting of a technical committee of the Interim Commission is now taking place in Cairo to consider revision of the clauses of the 1926 and 1938 conventions dealing with the Mecca pilgrimage, and on April 21 the expert committee on malaria met in Geneva. The expert committee on lists of causes of death and morbidity met in Ottawa last month.

If we look back over the twelve months since the technical preparatory committee met in Paris in March, 1946, the progress made is seen to be gratifying and unprecedented. A constitution for a World Health Organisation has been signed by 63 nations. An interim commission to carry on the urgent and statutory duties pertaining to world health has been working effectively for the past six months. The Paris Office, the Health Organisation of the League of Nations, and the Health Division of Unrra have been in practice absorbed, and their work carried on without serious interruption. Considerable progress has been made with the integration with the Pan-American Sanitary Bureau. Ten States-members of the United Nations and 3 non-members have ratified the constitution, and the progress reported of other ratifications is such that the necessary 26 will almost certainly be obtained before the end of the year.

A PIONEER OF SOCIAL DYNAMICS

ONE of the clearest and simplest formulations of Kurt Lewin, whose obituary we publish this week, was his distinction between the scientific concepts of Aristotle and Galileo. In dynamics Aristotle emphasised the nature of the object: he held that a stone fell to the ground because it was "earth" and had therefore to go towards the earth. Galileo, on the other hand, made physicists pay more attention to the object's relation to its environment. According to Aristotelian thought the environment played a part by "disturbing" the processes which follow from the nature of the object concerned; but in Galileian thought it is the concrete whole, which comprises the object *and* the situation, that determines the dynamics of the event defined: that is to say, an object is always in and part of its environment—an obvious notion but one with far-reaching implications if taken literally and always applied.

Its application to medicine is plain. We cannot isolate a person from his environment. When we examine an individual we are also examining a part of a genetic and a social field at the same time, if our ways of thought are thorough. When a patient comes to us our training leads us to see an object with an extension in time: it begins as a speck smaller than a pin's head, and ends some day as a life-size corpse. That speck grows by reason of forces in the cell and in the tissues in which it is embedded; that embryo, that child, develops through adolescence to adulthood and withers in old age: we see on examination at any one time a small slice in that

long history, but we also see one event which displays the interaction of forces within the organism and of those outside it—and knowledge of both are necessary for the understanding of that event before us, the patient in the *consulting-room.*

Our work requires that we "take a history," but in making our investigation, in so far as we use the methods of science, our mode of thought is a-historical: in other words, *we consider exhaustively what is happening here* and now, what is observable here and now, how we might by laboratory or other techniques extend our knowledge of the events occurring here and now. We do not, in so far as we are scientists, think of the patient as belonging to a "type," as Aristotle would have done, but as a product of forces operating in an interconnected set of fields, which (to use Lewin's term) is to employ a Galileian mode of thought. This does not deny us the right to use intuition, or "hunches," or any other process of thought, including a "feeling for" those historical developments which lead to present events; but the Galileian mode of approach does impel us to check our hunches a-historically—i.e., by the fullest observation of events occurring here and now.

The point of entry into a problem does not necessarily determine its point of emergence. As doctors we know this in our dealing with patients; they come to us for relief from pain (physical and mental), and that is our point of entry into their private world. Our treatment of them, however, is essentially an effort to improve their internal stability and external adaptability—which includes relief from the pain. Lewin applied the same principles to social problems. Here the point of entry was some symptom of social unrest, and from that starting-point he made a study of social dynamics with the aim of bringing about a stability in the social organisation he was advising. In yielding thus to the demands of "applied science" he did not feel that he was any the less a "pure scientist," for science is a method of thought and of testing ideas, and not an activity that can take place only in a region of social isolation. For Lewin, moreover, there could be no research without therapy, nor therapy without research, and his searching mind has given great help to those who try to assess the forces acting within the individual and within social groups.

DIETARY DEFICIENCIES IN HONG-KONG

THE period of the Japanese occupation was the blackest in the history of Hong-Kong; the exodus to the mainland and starvation with its attendant diseases reduced the population from its pre-war 1,500,000 to 500,000; many buildings were destroyed in the fighting in 1941 and later through bombing.

Dr. Selwyn-Clarke,[1] who remained on the island during the occupation as director of medical services, describes how most of the Europeans, Americans, and Indians were housed in Stanley internment camp. The 2500 *inmates included 40 doctors, 6 dentists, and 100 nurses,* so there was no shortage of trained medical staff. A hospital of 74 beds was set up at Tweedy Bay, but the extreme shortage of drugs and surgical material made the turnover very rapid. From the beginning the diet was poor, often consisting of half a pound of polished rice daily (sometimes deteriorating), with occasional beans, peanut-oil, and chrysanthemum leaves in place of green vegetables. Deficiency diseases soon appeared, the commonest being nutritional œdema (338 cases in 1942); this was closely followed by beriberi (the second commonest cause of death in Hong-Kong before the occupation), pellagra, and "central nerve blindness." The optic atrophy was an example of the "nutritional neuropathies" mentioned by Clarke and Sneddon[2] and others,[3] which also affected the tracts of the spinal cord, the peripheral and auditory nerves, and those supplying the vocal cords. This syndrome progressed from swelling round the ankles to weakness and paræsthesia of the limbs with difficulty in walking, seeing, and hearing. Lastly, the condition called "electric feet" was commonly seen, the sufferers finding that keeping their feet cool was the only effective treatment. The deficiency syndrome was *found in prisoners coming from all parts of the East,* but not in Europeans (however badly they were fed), though it was noted in Italian prisoners by Spillane and Scott[4] from the Near East, the common factor appearing to be a monotonous diet deficient in the vitamin-B complex. It responded poorly to vitamin therapy, suggesting that it is something more than a deficiency disease per se but is associated with an upset in carbohydrate metabolism and the formation of pyruvic acid. Harrison[5] has described a similar condition among Hong-Kong prisoners which he calls "painful feet"; this responded fairly well to vasodilators, suggesting that the immediate cause is vascular spasm.

Fehily,[6] who has compared the nutrition of Hong-Kong before and after the occupation, notes that signs of dietary deficiencies were unexpectedly mild when the island was reoccupied—in particular the widespread beriberi and pellagra foreseen did not materialise, though there were signs of general malnutrition. The relative freedom from gross deficiencies must have resulted mainly from the disappearance of highly milled rice and the necessity of eating whatever food was obtainable; in this one respect the Japanese occupation had a beneficial effect by breaking down many of the age-old food prejudices, some of which unfortunately tended to return when it again became possible to "corner" cereals or oranges and sell them at an exorbitant price. Nevertheless, thanks to the efforts of the relief workers, by a year after the liberation the infant mortality had fallen to 100 per 1000 live births, compared with the 327 per *1000 of 1940.*

THE ESKIMO'S TEETH

THE Eskimo was once held to be happily immune from the caries which ravages the teeth of other peoples; but he is immune no longer. In Greenland, it seems, we can study caries as a "new" disease, attacking a population with previously healthy teeth; and advantage has been taken of this opportunity by Dr. P. O. Pedersen, associate professor of dentistry at Copenhagen. Last week, speaking to the odontology section of the Royal Society of Medicine, he said that though caries is seen chiefly among the young, the older men and women, "whose teeth developed under Stone Age conditions," are not infrequently affected when they are brought into contact with civilised ways. The incidence is highest among those Eskimos employed by Europeans in the trading stations; thus at Julianehaab about 90% have one or more carious teeth. In East Greenland villages, where civilisation has made less headway, only about 5% are affected. The rise in incidence from nil, or almost nil (during the past fifty years in the west and still more recently in the east), has been associated with parallel changes in food habits. Formerly living on meat and fish, the Eskimo who adopts the white man's habits becomes a heavy consumer of carbohydrate; and "from whatever angle these principal results of the gigantic nutritional experiment forced upon the population of Greenland are surveyed it is beyond discussion that the natives who give up, more or less, the dietary habits of their ancestors and adopt white men's industrialised food are the ones who become afflicted with caries."

---

1. Selwyn-Clarke, P. S. Report on Medical and Health Conditions in Hong-Kong for the Period Jan. 1, 1942, to August 31, 1945. H.M. Stationery Office 1946.

Some may be quick to draw their own conclusions; but Dr. Pedersen enjoins caution: "In my opinion we are not entitled to draw far-reaching conclusions from these studies as to whether the tooth structure or the carbohydrate factor plays the greater part. . . . I do not think either that field studies of this kind will definitely solve the caries problem. In all probability the final effort will have to depend on the pure experiment."

A VERSATILE REMEDY

AMPHETAMINE or β-phenyl-iso-propylamine, better known as 'Benzedrine,' has been put to many uses since it was introduced in 1935. It was first applied to the treatment of narcolepsy,[1] for which it has proved unfailingly successful.[2] Though popular in Britain, the drug has received still more attention abroad, particularly in the United States; and reports testify to its value in such diverse conditions as depression, fatigue, postural hypotension, alcoholism, postencephalitic parkinsonism, epilepsy, obesity, sea-sickness, and behaviour disorders of children. It was soon apparent that this sympathomimetic amine was a central nervous stimulant, producing delay in the desire for sleep and subjective improvement in mood; and since one of its side-effects is to decrease appetite it has naturally found favour in the treatment of obesity. It has also been commended as a remedy for the postalcoholic "hangover." In some disorders, however, its value is still imperfectly defined, as was shown by the correspondence following an account in these columns of its use in pulmonary tuberculosis.[3]

Amphetamine's place in the treatment of adult psychopaths was discussed last week before the Society for the Study of Addiction by Dr. Denis Hill and Dr. H. J. Shorvon. Bradley and Bowen,[4] and Cutts and Jasper[5] have shown that amphetamine improves emotional control in children with hyperkinesis, temper tantrums, and enuresis. Many of these have an abnormal electroencephalogram, characterised by excess theta rhythm; and Hill, postulating the same constitutional background, has treated with amphetamine adult aggressive psychopaths with a "theta-persistent" E.E.G. Among 8 patients studied for four years he has observed improvement in the predominantly aggressive, bad-tempered, intolerant, easily frustrated, irresponsible psychopaths who are yet capable of warm interpersonal relationships. The effect is particularly impressive in a smaller but well-defined subgroup of aggressive psychopaths with the stigmata of very deep sleep, late cessation of nocturnal enuresis, excessive or morbidly excitable sexual appetite, and immature E.E.G. Shorvon, unlike Hill, has also found the drug of value in some inadequate psychopaths. Both emphasise the amazing tolerance of the predominantly aggressive psychopath to large doses; even such amounts as 45–60 mg. daily do not disturb sleep; during treatment libido is reduced and tempers are better controlled. Hill makes the interesting suggestion that there may be a link between Myerson's[6] anhedonic neurosis, with its "diminution, even to the point of disappearance, of the satisfactions normally obtained from life's activities and loss or distortion of the appetites and desires," and the beneficial effect of amphetamine in reducing libido, appetite, and aggression—that is, "the appetitive drives." Mann and Quastel[7] have shown by in-vitro experiments that amphetamine stimulates by neutralising the inhibitory action of amines during cerebral respiration; the E.E.G. of the aggressive psychopath shows cerebral immaturity, and amphetamine may produce a more mature expression of the primary appetitive drives by its effect on cortical oxidation.

In the late war enormous quantities of amphetamine were supplied to the Allied Forces, mainly for use in emergencies when it might be necessary to diminish fatigue and to postpone sleep. At last week's meeting, Prof. R. C. Browne reported that, while it combated some of the deterioration in the anoxæmic airman's performance and had a statistically significant action on sleeplessness, it caused no consistent improvement in the fatigued pilot's performance; with it, skilled function was, if anything, rather less good. Dr. H. Crichton-Miller and Dr. G. R. Rudolf agreed that amphetamine's effectiveness against fatigue is enhanced by glucose; but Crichton-Miller's view that its main action "is associated with the mobilisation of blood-sugar" is not endorsed by other workers,[8] most of whom have found little or no rise in blood-sugar. Rudolf recommends that the glucose should be taken six or seven hours after amphetamine, to counteract the postponed fatigue.

With judicious use, signs of idiosyncrasy or other reactions are rarely seen. Acute hallucinosis[9] and a paranoid or toxic psychosis have very rarely been recorded after continued large doses; but most patients, such as narcoleptics and psychopaths, who take it continuously for years, display neither toxic signs nor increased tolerance. They can, moreover, discontinue the drug abruptly without craving or other withdrawal symptoms.

METHYL ALCOHOL POISONING

THE war in Norway provided ample opportunities for the clinical study of poisoning by methanol, and a monograph by Röe[10] is based on 82 cases treated in various hospitals in or near Oslo. Though methanol does not as a rule provoke acidosis in experimental animals, Röe's observations lead him to believe that in man the outcome in cases of poisoning hinges entirely on the degree of acidosis, and in treatment he puts much emphasis on bicarbonate. Another of his conclusions is that ethyl alcohol counters the effects of methanol: his case-records show that the patients who suffered least were those who had mixed their drinks. In this connexion he writes: "It has been ascertained that when methanol alone is consumed, the latent period for the appearance of signs of poisoning is from 12 to 24 hours, usually 18 hours. Prolongation of the latent period beyond 24 hours is always due to the consumption of ethyl alcohol." Also he has a tilt at the teaching that individual predisposition is a factor of great importance.

G.M.C. ELECTION

OWING to the death of Sir Kaye Le Fleming there is a vacancy on the General Medical Council for a direct representative of the medical profession in England. The following have offered themselves as candidates:

Dr. JAMES BROWN, of Birmingham, member of the council of the British Medical Association.

Dr. J. E. OUTHWAITE, of Leeds, barrister-at-law, who stood at the election last June as a nominee of the Medical Practitioners Union.

Dr. ISAAC ROSE, of Leeds, medical officer at St. Helen Municipal Hospital.

* * *

Dr. P. S. Selwyn-Clarke, director of medical services, Hong-Kong, since 1938, has been appointed governor and commander-in-chief of the Seychelles. He has been a member of the executive and legislative councils of Hong-Kong.

ADVISERS IN NUTRITION TO THE CANADIAN ARMY OVERSEAS, 1942–46 *

DURING the late war the Canadian Army Overseas undertook an extensive programme based on the results of recent investigations of metabolism in injury and disease and designed to provide adequate nutrition for patients in its hospitals in the United Kingdom and Europe. This programme, outlined here, can be applied to civilian as well as military medicine.

The need for such a nutritional programme in hospitals was made obvious by the frequency with which weight-loss, representing tissue destruction, had been observed after injury and in disease (Taylor et al. 1943a, Elman 1944, Lund and Levenson 1945). Surveys of weight changes in military patients in hospital revealed that losses of 10–60 lb. were common (Lyons 1943, Stevenson et al. 1945a and b, 1946). Loss of weight in hospital patients is so common that it is usually considered an inevitable and unimportant accompaniment of injury and disease. However, recent investigations of metabolism following injury and in disease have shown that this loss of weight is due to malnutrition, which may seriously interfere with recovery; it is therefore neither inevitable nor unimportant.

BASIS OF NUTRITION PROGRAMME

Protein metabolism is disturbed after fractures, burns, infarctions, surgical operations, wounds, and various infections with or without fever (Cuthbertson 1942, Taylor et al. 1943b, Browne et al. 1944a and b, Peters 1944, Stevenson et al. 1945a, Grossman et al. 1945. There is increased catabolism of body protein, with excretion of large quantities of nitrogen in the urine, followed, after a variable period, by a tendency to increased anabolism of protein and replenishment of lost tissue. The first period of breakdown of protein tissue has been called by Browne et al. (1944b), Stevenson et al. (1945a) the protein catabolic period, and the second period of rebuilding of body protein tissue the protein anabolic period.

The loss of protein in the catabolic period cannot be explained by local-tissue destruction at the site of the pathological process, or even by loss of protein in its vicinity—e.g., muscular atrophy in a fractured limb (Cuthbertson 1942, Howard et al. 1944, Howard 1945). The catabolism of protein is increased throughout the body.

The increased catabolism of protein usually begins immediately after the onset of the damage, reaches its maximum during the first week, and, though gradually declining, persists for several weeks in serious injuries, when the patient gradually passes into the protein anabolic period. With moderate or severe injuries the duration and intensity of the protein catabolism are sufficient to cause appreciable weight-loss. Thus, in six cases of fracture the average total loss of protein amounted to 1400 g., equivalent to a loss of about 15 lb. of protein tissue (Howard et al. 1944).

The significance of the increased protein catabolism following damage is unknown. It is generally assumed that it is part of the response of the organism to damage and fulfils some useful purpose. It seems probable that the increased breakdown of protein makes available to the organism amino-acids and glucose, which may be useful in tissue repair or in furnishing energy for the body at a time when intake of food is apt to be low. There seems to be no reason to doubt that the significance of the subsequent anabolic period is replacement of body protein lost in the catabolic period.

Regardless of the significance of the increased catabolism of protein following damage, there is evidence that it may have deleterious effects, particularly if replenishment of tissue protein in the subsequent anabolic period is prevented or delayed by a low food intake, leading to loss of weight, involving protein tissues, such as liver and muscle, and to weakness. In some instances the loss of protein is further increased through transudates and exudates, as in burns, chest or bowel lesions, and any draining wounds (Taylor et al. 1943a, Hirshfeld et al. 1944, Co Tui et al. 1945, Lund and Levenson 1945). It is obvious that the greater the loss of weight and weakness the longer will be the convalescence, if death from inanition does not intervene (Elman 1944). There is also evidence that depletion of protein may interfere with wound healing and resistance to infection, and predispose to disturbances of gastro-intestinal function, liver damage, and shock (Mulholland et al. 1943b, Whipple and Madden 1944, Cannon 1945, Lund and Levenson 1945).

The obvious method of preventing or correcting depletion of protein in cases following damage and during convalescence is to increase the protein intake. At the same time the caloric intake must be increased; otherwise protein will be used to furnish energy, for energy requirements are known to be increased after damage. Daily intakes of 3500–4000 calories and 130 g. or more of protein are often required to prevent or correct rapidly the protein depletion (Mulholland et al. 1943a, Taylor 1944, Browne et al. 1944b, Stevenson et al. 1945a, Lund and Levenson 1945), even though the patient is confined to bed; and a daily intake of 2700 calories and 100 g. of protein should be regarded as the *minimum* required by convalescent patients.

These levels can be reached only by attention to all details necessary to ensure attractive and palatable meals of high nutritive value and by the use of supplementary feeds. Intravenous protein hydrolysates or tube feeding may be required in some cases. Though anorexia may make administration of a high diet difficult at first, feeding at a high level for a few days often leads to improvement in appetite (Elman and Akin 1945, Stevenson et al. 1945a).

If patients are fed at this level the net loss of protein from the body in the catabolic period may sometimes be reduced, and certainly restoration of body protein proceeds more rapidly in the anabolic period. Weight-losses, involving vital protein tissues, and associated weakness are thus prevented or reduced, and convalescence is shortened; there may also be a favourable effect on other consequences of protein depletion, such as delayed wound healing and lowered resistance to infection.

THE NUTRITION PROGRAMME

The nutrition programme, undertaken in hospitals of the Canadian Army Overseas, may be divided into four parts: (1) general educational measures; (2) surveys of food intakes of patients; (3) rules for three-meal diets, to obtain daily intakes of 100 g. of protein and 2700 calories; and (4) use of supplementary feeds to raise the total daily intake to any level necessary up to 130–170 g. of protein and 3200–3800 calories.

General Educational Measures.—Detailed information about the scientific basis of the programme, as outlined above, was disseminated among all medical officers, dietitians, and other hospital personnel by lectures, conferences, circular letters, and pamphlets. In this way a thorough understanding of the need for the programme was provided, and its importance, as part of the medical care of the patient, was emphasised.

---

* This appointment was held by E. H. B. in 1942–45 and by J. A. F. S. in 1945–46.

Surveys of Food Intakes of Patients.—To determine quantitatively the level of food intake of patients and the extent to which this must be increased to be adequate, surveys were made in three Canadian Army hospitals in the United Kingdom (X, Y, and Z), chosen at random. Convalescent surgical patients, free from gastro-intestinal disturbances and receiving ordinary diets, were chosen at random in each hospital. The foods offered to each of these patients at meals, and those portions returned uneaten, were weighed over a three-day period. The plates served were chosen at random so that the servings would represent those usually given by the nursing sister. The patients kept accurate lists of the food they ate between meals, such as supplementary feeds, canteen purchases, and items of parcels sent from Canada.

From these observations the protein, fat, carbohydrate, and calorie value of the food eaten each day by each patient was calculated with the tables of McCance and Widdowson (1942).

The average daily intakes of protein and calories of each patient, of each hospital group, and of the group as a whole are shown in table I. The results are broken down to show (A) the amount eaten from the three meals, (B) the amount eaten from supplementary (between-meal) feeds supplied by the hospital, (C) the total amount eaten from hospital sources (A+B), (D) the amount eaten from personal sources (not supplied by the hospital), and (E) the total amount eaten during the day (C+D).

The average results of the individual hospital groups, and of the group as a whole, indicated that feeding of patients in Canadian general hospitals in the United Kingdom was adequate, if judged on the basis of the nutritional requirements generally accepted until that time. It may also be said that the results compared very favourably with those of surveys carried out in civilian and military hospitals in Great Britain and North America (King Edward's Hospital Fund for London 1943, Stevenson et al. 1945b). However, satisfactory as the results were in this regard, they fell far short of what is now considered optimal for these patients and were even below the minimal requirement of 2700 calories and 100 g. of protein per day.

2	56	1882	7	162	63	2044	4	213	67	2257

The figures for individual intakes emphasised the lack of nutritional care of the individual patient. Only one of the patients (case 4, hospital X) had an intake approaching that now recognised as optimal. In many instances the intakes were below even the older standards of food requirements.

The average daily intake derived from the three meals for the group as a whole amounted to 69 g. of protein and 1976 calories only. Experience with high diets has shown that the desired intakes cannot readily be attained, even with special supplementary feeds, unless the three meals alone supply at least 100 g. of protein and 2700 calories daily.

The average daily intake derived from supplementary (between-meal) feeds for the group as a whole amounted to 14 g. of protein and 348 calories only. This is much lower than can be obtained by the properly regulated use of special supplementary feeds.

These data concern patients on ordinary diets only, but no better results were being achieved with patients for whom special "high" diets had been ordered. Thus, the food intake of two such patients, shown in table II, was much less than the prescribed diet, and in case 2 was less than the average intake of patients on ordinary diet. In fact, in this case the prescription of a high-protein low-fat diet led to the consumption by the patient of 67 g. of protein and 90 g. of fat a day!

The most serious and most common fault revealed by these investigations was the low food intake of most hospital patients, *even when well along in convalescence.* At this time, when a good appetite was the rule and the protein anabolic tendency predominated, the food intake was often so low, owing to poor quality, quantity, variety, preparation, and serving of food, and lack of education of the patient with regard to his nutritional requirements, that there could be no expectation that the protein deficit of the catabolic period would be rapidly replenished.

It was concluded from these surveys that steps must be taken to increase the protein and calorie intakes from the three meals, and to provide special high-protein high-calorie supplementary feeds, with detailed instructions concerning their use, if intakes of about 130–170 g. of protein and 3200–3800 calories were to be achieved where such levels were necessary to prevent or correct weight-loss.

The report of these surveys was distributed to all Canadian Army hospitals overseas. At the same time detailed instructions were issued about the means by which adequate food intakes of patients could be attained. These instructions were divided into two parts: those relating to the three meals, and those relating to supplementary feeds.

Rules for Three-meal Diets.—To obtain daily intakes of 100 g. of protein and 2700 calories from the three meals alone, the following instructions were issued:

(1) *Provision of diets:* the dietitian will provide ordinary diets planned so that the three meals will contain at least 100 g. of protein and 2700 calories a day.

Protein and calorie intake will be further increased, when necessary, by special supplementary feeds and not by changing the content of the three meals. High diets will therefore consist of these improved three meals of the ordinary diet plus special supplementary feeds served between meals.

Most of the items now served as supplementary feeds are to be included in the meals. Specifically, milk should be served as the beverage with meals rather than between meals. The between-meal periods will then be left free for special high-protein high-calorie supplementary feeds.

However, patients already at ideal weight, not seriously ill or injured, and therefore not requiring special supplementary feeds, may be given ordinary between-meal feeds, such as tea, cocoa, biscuits, and fruit juices.

(2) *Serving in wards:* dietitians will demonstrate to the nursing sisters the proper quantities per helping of each food to provide each patient with at least 100 g. of protein and 2700 calories in the three meals each day.

(3) *Supervision of feeding of patients:* no improvement in food intakes can be accomplished unless the doctor assumes his responsibility for the nutrition of his patients.

The doctor should personally explain to each patient the necessity of eating all the food offered him, and tell him that his failure to do so only prolongs his convalescence. Most patients think that, because they are in bed, their food requirements are small, whereas usually the opposite is true; this must be explained to the patient.

The doctor should visit his wards at mealtimes often, to observe the serving and consumption of the meals. Special attention should be paid to the amount of food left by the patient, and the causes of failure to eat all the food offered should be determined and eliminated.

Feeding problems should be discussed by the medical officer with the dietitian, nursing sister, and senior cook.

It is the special responsibility of the officers in charge of the medical and surgical divisions to ensure that their ward medical officers are fully aware of the importance of this nutritional supervision.

The level of food intake required in any case is judged on the basis of the severity of the injury or illness, and the maintenance or restoration of ideal weight. Changes in weight and tissue mass are best measured by regular weighing of the patient. In the many cases where this is impossible the nutrition can be fairly accurately judged by observation of the general appearance of the patient, the tenseness of the skin over the underlying tissues, the tightness of plaster-casts, or measurements of limb circumferences.

The success of this programme to improve the nutrition of patients depends entirely on the support it receives from the doctors; the desired increase in food intakes cannot be effected merely by sending more food from the kitchen to the wards, or by the haphazard ordering of supplementary feeds or special diets.

(4) *Responsibilities of nursing sisters:* attention must be paid to supervision of food intakes. Plate wastage must not be ignored or eliminated by reducing the amount served, but should be overcome by determining and correcting the cause—e.g., failure to report to the dietitian individual food dislikes of the seriously ill patient, failure to provide feeding aids and other assistance to patients unable to feed themselves easily, and delay in serving owing to poor discipline of ward help.

Use of supplementary feeds to raise the total daily intake to any level necessary up to 130–170 g. of protein and 3200–3800 calories.—In investigations of nutrition in convalescence carried out for the associate committee on Army medical research of the National Research Council of Canada, supplementary feeds composed of milk, milk powders, ice-cream, eggs, and flavourings had been found most useful in attaining high food intakes (Stevenson et al. 1945a). In view of the scarcity of these foodstuffs in the United Kingdom and Europe the Canadian Army in Canada and the Canadian National Research Council developed a powdered high-protein milk-shake mix and syrup flavourings suitable for shipment and use overseas (Stevenson et al. 1946). This powdered mix, obtained from milk, had the following food value per oz.:

Calories	123
Protein	9·0 g.
Fat	4·0 g.
Carbohydrate	12·7 g.

Five syrup flavourings (chocolate, vanilla, maple, strawberry, and pineapple) were provided. When reconstituted in the proportions of 4 oz. of powdered mix, 12 oz. of water, and 1 oz. of flavouring, the product had a volume of 16 oz. and furnished 36 g. of protein and 570 calories.† (The ordinary egg nog made with two eggs provides about 20 g. of protein and 200 calories only.) The powder was easily reconstituted with water, in bulk quantities if necessary, and, after refrigeration for at least an hour, yielded a very palatable drink. Flavourings were varied each day to avoid monotony. Further dilution with water usually overcame the objection of the occasional patient who found the regular recipe too rich.

The indication for the therapeutic use of the milk-shakes as supplementary feeds was a food requirement exceeding that supplied by the three meals. With the three meals providing a daily intake of at least 100 g. of protein and 2700 calories the total intake could readily be raised to about 170 g. of protein and 3800 calories by the use of 32 fluid oz. of reconstituted milk-shake. Clinical trial demonstrated that it was best to divide this into two feeds of 8 oz. each, given in the mid-morning and mid-afternoon, and one of 16 oz. given at bedtime.

These feeds were also very satisfactory as one of the major items in liquid diets. For this purpose they were often given in a more dilute form. They were also well suited to tube feeding.

CATERING PROGRAMME

It is useless to make demands for improved feeding of patients unless the catering organisation and equipment of the hospital are first made adequate to meet those demands. The nutritional programme described above was preceded and accompanied by a catering programme under the direction of the chief inspector of catering and the adviser in nutrition of the Canadian Army Overseas. The catering programme, which had been begun in early 1943, included the clarification of the duties and responsibilities of all hospital personnel concerned with the feeding of patients; the selection, training, and qualification of cooks; the provision, organisation, and discipline of kitchen help; the planning of menus; the standardisation and proper supervision of methods of storage, preparation, transport, and serving of food; the construction of kitchens; and the provision of kitchen, transport, and serving equipment. The main object of this catering programme was to ensure the provision of meals not only adequate in amount but also palatable and attractively served.‡

---

† A mixture of about the same composition can be prepared by mixing high-quality spray-dried skimmed-milk powder and fresh whole milk in suitable proportions, and adding flavouring to taste. Care must be taken in the selection of suitable skimmed-milk powder preparations and flavourings; products of inferior grade produce an unpalatable drink. Feeds could not be prepared on any large scale overseas during the war in this way, because supplies of these commodities were not available in the quantities required.

‡ *Civilian hospital catering* in U.K. was made the subject of a study in 1945 by the committee on hospital diet of the King Edward's Hospital Fund for London.

Each hospital carried on its staff a lieutenant-dietitian who was a university graduate and met the qualifications of the Canadian Dietetic Association. As the officer in charge of the patients' kitchen, she was responsible for drawing up menus, ordering foodstuffs from the steward, supervising their preparation, transport, and serving, and for the administration and further training of cooks. The dietitian must have full authority in all these fields if the catering is to be efficient. She must also have direct contact with patients, doctors, nurses, and the administrative head of the hospital. The importance of a well-trained and experienced dietitian, alive to the fact that patients must be "sold" their food in the same way as restaurant customers, and with complete authority over catering for patients, cannot be too strongly emphasised.

In most hospitals maintenance of a low cost of food and catering is regarded as a sign of efficiency. This attitude, which was prevalent in the Canadian Army as elsewhere, is not compatible with a high standard of medical care. Every effort was therefore made to substitute for it the concept that efficiency should be judged on the basis of the provision of adequate nutritional care for the patients.

The value of such a catering programme, under the supervision of an experienced caterer and a medical nutritionist, can be demonstrated by comparing the results of surveys of food intakes of patients reported here with the results of those made in military hospitals in Canada (Stevenson et al. 1945b). The overseas surveys reported here were done after the catering programme was well under way, whereas no special emphasis had been laid on hospital catering in Canada before the surveys conducted there. Though rations in Canada were much more liberal, both in quantity and variety, than those available in the United Kingdom, the food intakes in Canadian Army hospitals in Canada were actually lower than food intakes in Canadian Army hospitals in Britain. Thus, in Canada the average daily intake from hospital sources amounted to 64 g. of protein and 2064 calories (Stevenson et al. 1945b),[§] whereas the corresponding figures for the United Kingdom were 83 g. of protein and 2324 calories (table I).

SUMMARY

An outline is given of the nutritional programme undertaken in the hospitals of the Canadian Army Overseas during the late war.

The purpose of this programme was to raise the standard of nutritional care of patients to that considered optimal in the light of recent investigations of metabolism in injury and disease.

The scientific basis of the programme, the results of surveys of food intakes of patients, the measures used to attain the standards required, and the associated catering programme are described.

The investigations revealed that the food intake of most hospital patients was far too low, even when patients had recovered sufficiently to regain their appetite.

It seemed necessary to increase the protein and calorie intakes from the main meals, and to provide supplementary feeds of high-protein and high-calorie content, such as the milk-shakes described.

The value of similar programmes in most civilian hospitals is obvious, but they require supervision by an experienced caterer and a medical nutritionist, and involve a reorientation and reorganisation of the professional and technical staff of the hospital, in so far as the feeding of patients is concerned.

[§] A second survey of food intakes in Canadian Army hospitals in Canada, done nine months later, following implementation of an intensive nutritional and catering programme, showed a well-marked improvement (Stevenson et al. 1946).

Medicine and the Law

A Name Misheard

THE newspapers have lately described a case in which confusion between the words "procaine" and "cocaine" led to a fatal accident and raised questions of liability for negligence. Mr. Justice Hilbery dealt with the facts in deciding the case of Collins *v.* Hertfordshire County Council and King last month. The circumstances, he said, were so extraordinary that he could not believe they were ever likely to occur again. Hospital managements, it may be added, will be alert to see that they do not.

A patient entered the Wellhouse Hospital at Barnet for an operation on his jaw. Arranging to give an injection before operating, the surgeon telephoned an instruction to have ready 100 ml. of 1% procaine and 1/200,000 adrenaline. The message was taken by a student (not then qualified) acting as student house-surgeon; she misheard the instruction and asked the hospital pharmacist to prepare a solution containing 1% cocaine. The operating surgeon injected 80 ml. of this solution—some four times the lethal dose—and the patient died. The widow claimed damages both from the county council (as the owners of the hospital) and from the surgeon who gave the injection.

The defendant surgeon stated in evidence that he himself always called the drug "procaine." The term 'Novocain,' adopted by German manufacturers as its trade name, had been commonly employed; but at the beginning of the late war the medical profession had been asked not to use it. He had never known of cocaine being given by injection, and he had no idea that he had injected it. He could not understand an experienced pharmacist dispensing so large a quantity of a dangerous drug; the amount of adrenaline was unusual, and the pharmacist should have queried it. The regulations, said the surgeon, require that dangerous drugs be dispensed only on the written instructions of a qualified medical practitioner; the pharmacist had dispensed this solution to an unqualified person without referring the matter back to himself or insisting on the signature of a qualified practitioner.

The judge found that the surgeon who gave the instructions by telephone and who made the injection was negligent. The surgeon had expected the student house-surgeon who took the message to use her knowledge and reason and to apply her mind to what he was saying; but still the surgeon himself was responsible for not making sure that he was getting what he had ordered. The student house-surgeon, continued the judge, was

negligent; she knew that the solution was required for an injection and she knew that the solution as prepared was lethal; she had not used reasonable skill or care. Further, the pharmacist was negligent. He had accepted an oral demand for an exceptional dosage of cocaine and adrenaline for injection and had not required the order to be initialled by a qualified person; he had not checked the demand with the surgeon; and he had disregarded all the prescribed safeguards, including the cautionary instruction in the *British Pharmacopœia* that when an unusually large dose of a drug appears to have been prescribed the pharmacist or dispenser should satisfy himself that the prescriber's intention has been correctly interpreted. Finally the judge found the hospital responsible. It was liable for the negligence of its two employees (the student house-surgeon and the pharmacist), and it had failed to establish a proper system and to insist upon obedience to the rules about dangerous drugs. "If the hospital had had a proper system, this solution could not have arrived at the operating-theatre, let alone the body of the unfortunate patient." The judge awarded £2500 damages and directed that payment be borne equally by the county council (as owners of the hospital) and the surgeon.

It will be remembered that the risk of confusion between procaine and the proprietary preparation 'Percaine' was dealt with by the manufacturers of the latter changing its name to 'Nupercaine' (*Lancet* 1942, ii, 221, 340). As Mr. Justice Hilbery deemed the circumstances in the Collins case unlikely to recur, there seems no need to rechristen all our dangerous drugs with names chosen, like those of the London telephone exchanges, for their distinctive enunciation, so as to avoid all possible risk of misunderstanding. With ordinary and proper care these accidents will not happen, even when hospital staffs are overworked and undermanned.

Public Health

Tuberculosis in Lancashire

FOR the purpose of treating tuberculosis the administrative county of Lancaster is divided into 8 areas—5 large, 3 small. Each large area is in charge of a team made up of a consultant tuberculosis officer, one or more assistant tuberculosis officers, 4–7 health visitors, and 2 clerks. The area served by the team has a chief dispensary, two or more branch dispensaries, and a sanatorium-hospital of up to 70 beds for treatment and isolation of patients near their homes. The consultant acts as visiting medical superintendent of the hospital. One of the three small dispensary areas is in the charge of the medical superintendent of High Carley Sanatorium (154 beds), and another under the superintendent of the Elswick Sanatorium (70 beds). In the third dispensary area, adjoining Wrightington, the tuberculosis officer has been appointed visiting physician to the 74 beds in the pulmonary section of Wrightington Hospital. Thus all senior or consultant tuberculosis officers have institutional beds, like consultants in other branches of medicine; and Dr. F. C. S. Bradbury, the central consultant tuberculosis officer of the county, believes that this combination of hospital, dispensary, and domiciliary practice enables them to see the problem of tuberculosis treatment and prevention whole.

In his report [1] for 1945, which has just appeared, 709 deaths from pulmonary tuberculosis and 161 deaths from non-pulmonary tuberculosis are recorded—the lowest figures ever achieved in Lancashire, giving death-rates of 0·38 and 0·08 per 1000 population. New cases of pulmonary tuberculosis, however, amounted to 1511, a figure as great as the high record of the previous year. Non-pulmonary tuberculosis notifications reached a record low level (641 cases); and the case-rates for the two forms were 0·82 and 0·34 per 1000 population. Though the death-rates are the best yet recorded, they are probably higher than they would have been but for the war. The rise in deaths from tuberculosis in 1940–41 was probably due to the failure of many patients to survive increasing hardship. War must be blamed, too, for the fact that death-rates in subsequent years have not fallen as fast as they should: patients with pulmonary tuberculosis could not give themselves the necessary care and protection; and non-pulmonary tuberculosis—including meningitis—increased not only because children and others were exposed to infection from sputum-positive adults in crowded ill-ventilated billets and shelters, but also because many patients stayed in their homes owing to lack of sanatorium beds.

The Lancashire mass-radiography unit had made eight surveys up to Jan. 16, 1946, the results of which are analysed in the report.

In all, 74,208 factory workers were examined in this way. Active pulmonary tuberculosis was found in 239 (3·2 per 1000 examined), and healed pulmonary tuberculosis in 1515 (20·4 per 1000). Of 500 cases classed as "inactive tuberculosis" (in which the lesion seemed to be healed or healing, but which needed further investigation), 301 were referred to a dispensary, 165 to their own doctor, and 34 refused treatment. These findings indicate, Dr. Bradbury considers, that, in addition to the incidence of pulmonary tuberculosis notified through the ordinary channels, there is an equal incidence, in those age and sex groups represented by factory workers, of which we have no knowledge apart from mass radiography. Two age-groups were specially concerned in these surveys: men over 45 and women under 25. Dr. Bradbury concludes that mass radiography or other intensive methods of investigation should be extended to groups of the population among whom unknown cases are even more likely to be found than among factory workers.

Good results with calciferol in the treatment of lupus vulgaris are recorded by Dr. E. H. W. Deane, and the report also contains an analysis of the after-history for five years of 2200 new cases of tuberculosis notified in 1940. The net number of these treated under the county tuberculosis scheme was 1810, 1178 of these being cases of pulmonary tuberculosis. Lest a low-record death-rate should mislead any into a belief that tuberculosis is controlled, it is worth recalling what this disease means for the patient, even in a county like Lancashire, which has developed a good scheme. Of 1027 pulmonary cases in the survey (removals from the area excluded) 58·3% died from tuberculosis within five years, and 33·6% were still under treatment at the end of that time.

Smallpox

No further cases have been reported up to April 22. The foci at Grimsby, Stepney, and Doncaster were controlled by surveillance and vaccination of close contacts, and are believed to be extinct. At Scunthorpe the total number of confirmed cases is 7; the last was removed on April 12 (onset April 7, rash April 12). At Bilston the position is unchanged. The last of the 8 patients died at home in the prodromal stage on April 11. The last removals to hospital were on April 10.

In New York, where, according to British United Press, there have so far been 10 cases with 2 deaths, vaccine for 5 million people has been provided; and some 67,000 have already been vaccinated. The outbreak began with the death of a Mexican business man on March 10; subsequent cases have been traced to a child who was transferred from the hospital where this man died. The *Daily Telegraph* reports that visitors from Europe who are unable to produce written evidence of having been vaccinated within the past three years are now required to undergo vaccination before landing in the United States.

Infectious Disease in England and Wales

WEEK ENDED APRIL 12

Notifications.—Smallpox, 13; scarlet fever, 928; whooping-cough, 1751; diphtheria, 213; paratyphoid, 1; typhoid, 6; measles (excluding rubella), 10,326; pneumonia (primary or influenzal), 709; cerebrospinal fever, 89; poliomyelitis, 11; polioencephalitis, 0; encephalitis lethargica, 0; dysentery, 77; puerperal pyrexia, 156; ophthalmia neonatorum, 61. No case of cholera, plague, or typhus was notified during the week.

Of the 13 cases of smallpox, 5 were notified at Scunthorpe and 8 at Bilston, Staffs.

Deaths.—In 126 great towns there were no deaths from enteric fever or scarlet fever, 1 (0) from diphtheria, 12 (1) from measles, 26 (4) from whooping-cough, 85 (14) from diarrhœa and enteritis under two years, and

---

[1] Prevention and Treatment of Tuberculosis in the Administrative County of Lancaster. Report of the Tuberculosis Services of the Lancashire County Council for the year 1945.

33 (7) from influenza. The figures in parentheses are those for London itself.

The number of stillbirths notified during the week was 246 (corresponding to a rate of 23 per thousand total births), including 35 in London.

Parliament

ON THE FLOOR OF THE HOUSE

THE Chancellor's Budget was in some ways better than was expected, and the income-tax concessions are of value to many people. The solar-plexus blow of the increase in the duty on tobacco took Members' breath away, but one financial authority was heard to mutter—not loud enough to get into *Hansard*—that the income-tax concessions would just about pay his tobacco and cigarette account. We shall have to wait a year to find out how many people in fact will reduce their consumption. Smoking increased sharply during the war, and the psychology of the war years has not changed back to normal. The Chancellor hopes that smokers will cut down their consumption by a quarter. But psychological estimates are not made so accurately as financial ones, and if he is wrong we shall increase the proportion of our income we spend on tobacco and save no dollars. To save dollars is the Chancellor's professed aim, and many Members are asking, in the lobbies, if not in the House, whether it would not have been simpler to cut down tobacco imports by a half or a quarter, and (if practicable without undue waste of man-power) ration cigarettes and tobacco just as we ration sweets. The severe winter has made it even more important to save dollars; for many sheep and cattle have died, many clamps of potatoes have been destroyed, the sowing season was postponed, and our food-supplies not only for next winter but for 1949 are seriously depleted. If we spend too many dollars on tobacco—and incidentally on American films—we shall not have enough to buy food in dollar markets. There is need of the greatest care and economy to avoid actual food shortage in the near future.

Sir John Anderson, who was Chancellor under the Coalition Government, criticised Mr. Dalton severely and drew attention to the large sum of £425 million which is being spent on subsidies to keep price-levels stable—largely price-levels of food. But the proof of this pudding is definitely in the eating. A comparison of our costs of living, plus the subsidies, with costs of living in the many countries of the world where inflation rages like an acute pyrexia, is in our favour.

FROM THE PRESS GALLERY

Third Reading of Scottish Bill

On April 21 the House of Commons considered the amendments made to the National Health Service (Scotland) Bill in committee, and then passed directly to the third reading, which was completed before the House rose.

The finishing touches made in committee included a new clause permitting a local health authority to make provision for research relating to their functions. As examples of the kind of research the clause would cover, Mr. J. J. WESTWOOD cited studies into the effectiveness of forms of care given at child-welfare centres and inquiries into the effects of environment on health. A further new clause gave local health authorities power to contribute to expenditure on coördination of services. This clause was inserted to encourage the formation of non-statutory local committees in which representatives of the three divisions of the new service would take part.

An amendment to clause 5 laid down that the accommodation set aside in hospitals for private patients must not reduce the number of beds available free of charge immediately before the new service came into operation. An amendment was also inserted in clause 8 ruling that hospital endowments must be used with due regard to—

> "the spirit of the intention of the founder or donor of the endowment to which the scheme relates and in particular to conditions intended to preserve the memory of any person or class of persons;
>
> "the extent to which the original purpose of the endowment is sufficiently provided for by a public service or otherwise; and
>
> "the interests of the hospital and specialist services."

Mr. Westwood, moving the third reading, said the Bill achieved a major reform, and this inevitably had meant the displacement of both the voluntary and local-authority hospital systems, but he believed that both retained a proper place in the hospital organisation of the future. The Bill made it easy for the biggest number of hospitals to come within the teaching field and to share in the advantages which that work conferred, and without trespassing on their responsibilities it brought the teaching and licensing authorities into the administration of the hospital service. Building on the foundation that the duty of the local authorities was to watch over the incidence of disease, the Bill gave them power for important developments in the prevention of disease and the treatment of health in the community life. It also enabled the Minister to arrange for everyone to have the care and attention of the family doctor of their choice without need to count the cost. But it gave the Minister no power to direct individual doctors to work in particular localities at particular jobs. The Bill would not produce more doctors overnight, but Mr. Westwood believed that the new system of remuneration, and abolition of the sale and purchase of practices, would improve the attraction of general medical practice as a career, and that the measure to bring further education within the reach of all would produce at no distant date an adequate number of doctors.

Colonel WALTER ELLIOT moved an amendment criticising the Bill for its centralisation of control. Such a change, he declared, would only be justified if the medical system of Scotland had been a signal failure instead of admittedly one of the great scientific and practising successes of the world. The people of Scotland did not lack medical advice, but they had the greatest difficulty in carrying out that advice, and the Bill did not take a single sensible step towards remedying this. The principles on which it was based would threaten not only the practice of medicine but the research upon which this practice depended. Mr. HENDERSON STEWART recognised that the State had great functions to perform, but they did not include, he suggested, the intimate day-to-day control of detailed services of this kind. While Mr. J. RANKIN applauded the training given to medical students, he asserted that the young doctor emerged into the world to face complete anarchy. Neither his medical school nor the British Medical Association took the slightest interest in placing that young lad in any post. The Bill would absorb at once into active useful work every young doctor who left the universities.

Lady GRANT suggested that the Bill gave us a rigidity of administration unsuited to the living human art of caring for the sick, and Commander T. D. GALBRAITH feared that over-centralisation would bring in its train uniformity and standardisation. Dr. H. B. MORGAN thought the Bill better than the English one. Mr. G. BUCHANAN, in summing up, said at present we only had a partial service, but the Bill would offer everyone a modern service without restriction.

QUESTION TIME

Panel Dentistry

Mr. G. C. TOUCHE asked the Minister of National Insurance if he was aware of the inconvenience caused to panel patients by their inability to get dental treatment owing to the prolonged dispute about dentists' fees; and if he would make a statement on the subject.—Mr. T. STEELE replied: As the House was informed at the time, agreement on the payments to be made for National Health Insurance work was reached with the Joint Advisory Dental Council of the profession towards the end of last year. In accordance with that agreement the council advised, and continues to advise, members of the profession generally to resume the practice of accepting insured persons for treatment in accordance with the Dental Benefit regulations. The Minister is aware that a number of dentists who have given treatment under the regulations in the past have not yet followed this advice of their negotiating body and he is sorry that because of this insured persons in some areas are still having difficulty in obtaining dental benefit. But the general position is improving steadily and he thinks he must leave it to the council to continue their efforts to secure a satisfactory service for insured persons in all areas under the terms of the agreed settlement.

negligent; she knew that the solution was required for an injection and she knew that the solution as prepared was lethal; she had not used reasonable skill or care. Further, the pharmacist was negligent. He had accepted an oral demand for an exceptional dosage of cocaine and adrenaline for injection and had not required the order to be initialled by a qualified person; he had not checked the demand with the surgeon; and he had disregarded all the prescribed safeguards, including the cautionary instruction in the *British Pharmacopœia* that when an unusually large dose of a drug appears to have been prescribed the pharmacist or dispenser should satisfy himself that the prescriber's intention has been correctly interpreted. Finally the judge found the hospital responsible. It was liable for the negligence of its two employees (the student house-surgeon and the pharmacist), and it had failed to establish a proper system and to insist upon obedience to the rules about dangerous drugs. "If the hospital had had a proper system, this solution could not have arrived at the operating-theatre, let alone the body of the unfortunate patient." The judge awarded £2500 damages and directed that payment be borne equally by the county council (as owners of the hospital) and the surgeon.

It will be remembered that the risk of confusion between procaine and the proprietary preparation 'Percaine' was dealt with by the manufacturers of the latter changing its name to 'Nupercaine' (*Lancet* 1942, ii, 221, 340). As Mr. Justice Hilbery deemed the circumstances in the Collins case unlikely to recur, there seems no need to rechristen all our dangerous drugs with names chosen, like those of the London telephone exchanges, for their distinctive enunciation, so as to avoid all possible risk of misunderstanding. With ordinary and proper care these accidents will not happen, even when hospital staffs are overworked and undermanned.

Public Health

Tuberculosis in Lancashire

FOR the purpose of treating tuberculosis the administrative county of Lancaster is divided into 8 areas—5 large, 3 small. Each large area is in charge of a team made up of a consultant tuberculosis officer, one or more assistant tuberculosis officers, 4–7 health visitors, and 2 clerks. The area served by the team has a chief dispensary, two or more branch dispensaries, and a sanatorium-hospital of up to 70 beds for treatment and isolation of patients near their homes. The consultant acts as visiting medical superintendent of the hospital. One of the three small dispensary areas is in the charge of the medical superintendent of High Carley Sanatorium (154 beds), and another under the superintendent of the Elswick Sanatorium (70 beds). In the third dispensary area, adjoining Wrightington, the tuberculosis officer has been appointed visiting physician to the 74 beds in the pulmonary section of Wrightington Hospital. Thus all senior or consultant tuberculosis officers have institutional beds, like consultants in other branches of medicine; and Dr. F. C. S. Bradbury, the central consultant tuberculosis officer of the county, believes that this combination of hospital, dispensary, and domiciliary practice enables them to see the problem of tuberculosis treatment and prevention whole.

In his report [1] for 1945, which has just appeared, 709 deaths from pulmonary tuberculosis and 161 deaths from non-pulmonary tuberculosis are recorded—the lowest figures ever achieved in Lancashire, giving death-rates of 0·38 and 0·08 per 1000 population. New cases of pulmonary tuberculosis, however, amounted to 1511, a figure as great as the high record of the previous year. Non-pulmonary tuberculosis notifications reached a record low level (641 cases); and the case-rates for the two forms were 0·82 and 0·34 per 1000 population. Though the death-rates are the best yet recorded, they are probably higher than they would have been but for the war. The rise in deaths from tuberculosis in 1940–41 was probably due to the failure of many patients to survive increasing hardship. War must be blamed, too, for the fact that death-rates in subsequent years have not fallen as fast as they should: patients with pulmonary tuberculosis could not give themselves the necessary care and protection; and non-pulmonary tuberculosis—including meningitis—increased not only because children and others were exposed to infection from sputum-positive adults in crowded ill-ventilated billets and shelters, but also because many patients stayed in their homes owing to lack of sanatorium beds.

The Lancashire mass-radiography unit had made eight surveys up to Jan. 16, 1946, the results of which are analysed in the report.

In all, 74,208 factory workers were examined in this way. Active pulmonary tuberculosis was found in 239 (3·2 per 1000 examined), and healed pulmonary tuberculosis in 1515 (20·4 per 1000). Of 500 cases classed as "inactive tuberculosis" (in which the lesion seemed to be healed or healing, but which needed further investigation), 301 were referred to a dispensary, 165 to their own doctor, and 34 refused treatment. These findings indicate, Dr. Bradbury considers, that, in addition to the incidence of pulmonary tuberculosis notified through the ordinary channels, there is an equal incidence, in those age and sex groups represented by factory workers, of which we have no knowledge apart from mass radiography. Two age-groups were specially concerned in these surveys: men over 45 and women under 25. Dr. Bradbury concludes that mass radiography or other intensive methods of investigation should be extended to groups of the population among whom unknown cases are even more likely to be found than among factory workers.

Good results with calciferol in the treatment of lupus vulgaris are recorded by Dr. E. H. W. Deane, and the report also contains an analysis of the after-history for five years of 2200 new cases of tuberculosis notified in 1940. The net number of these treated under the county tuberculosis scheme was 1810, 1178 of these being cases of pulmonary tuberculosis. Lest a low-record death-rate should mislead any into a belief that tuberculosis is controlled, it is worth recalling what this disease means for the patient, even in a county like Lancashire, which has developed a good scheme. Of 1027 pulmonary cases in the survey (removals from the area excluded) 58·3 % died from tuberculosis within five years, and 33·6% were still under treatment at the end of that time.

Smallpox

No further cases have been reported up to April 22. The foci at Grimsby, Stepney, and Doncaster were controlled by surveillance and vaccination of close contacts, and are believed to be extinct. At Scunthorpe the total number of confirmed cases is 7; the last was removed on April 12 (onset April 7, rash April 12). At Bilston the position is unchanged. The last of the 8 patients died at home in the prodromal stage on April 11. The last removals to hospital were on April 10.

In New York, where, according to British United Press, there have so far been 10 cases with 2 deaths, vaccine for 5 million people has been provided; and some 67,000 have already been vaccinated. The outbreak began with the death of a Mexican business man on March 10; subsequent cases have been traced to a child who was transferred from the hospital where this man died. The *Daily Telegraph* reports that visitors from Europe who are unable to produce written evidence of having been vaccinated within the past three years are now required to undergo vaccination before landing in the United States.

Infectious Disease in England and Wales

WEEK ENDED APRIL 12

Notifications.—Smallpox, 13; scarlet fever, 928; whooping-cough, 1751; diphtheria, 213; paratyphoid, 1; typhoid, 6; measles (excluding rubella), 10,326; pneumonia (primary or influenzal), 709; cerebrospinal fever, 89; poliomyelitis, 11; polioencephalitis, 0; encephalitis lethargica, 0; dysentery, 77; puerperal pyrexia, 156; ophthalmia neonatorum, 61. *No case of* cholera, plague, or typhus was notified during the week.

Of the 13 cases of smallpox, 5 were notified at Scunthorpe and 8 at Bilston, Staffs.

Deaths.—In 126 great towns there were no deaths from enteric fever or scarlet fever, 1 (0) from diphtheria, 12 (1) from measles, 26 (4) from whooping-cough, 85 (14) from diarrhœa and enteritis under two years, and

Letters to the Editor

TUBERCULOSIS AND THE NATIONAL HEALTH SERVICE ACT

SIR,—The names of the members of the regional boards may be published at any moment, and as soon as appointed they will have to get to work on the new organisation due to operate from next April. We also see that on July 8 the Minister of Health himself is to address the Commonwealth and Empire Health and Tuberculosis Conference (arranged by the National Association for the Prevention of Tuberculosis) on the National Health Service Act and its Effect on Tuberculosis Schemes.

Tuberculosis, because of its effect not only on the patient but on the community, presents special problems and difficulties, as is generally admitted: we note that the Minister of Health and the Minister of National Insurance have accepted the position that pulmonary cases will qualify for extra benefits, and the Ministry of Labour are planning special workshops for the tuberculous. No scheme for the prevention and treatment of tuberculosis can ever be efficient and effective unless the family is regarded as the unit. If separate medical staffs undertake separate parts of what should be a unified tuberculosis scheme, then we shall surely see return a state comparable with the days before the Astor report.

Leading officials of the Ministry of Health have stated that it is the full intention to continue the best features of efficient tuberculosis schemes. How, then, can we ensure within the framework of the new Act the greatest possible integration of the several components which ought to constitute a workable and successful regional organisation? I would like to make the following suggestions.

(1) The Minister of Health, after consultation with the Central Health Services Council, should have a Tuberculosis Advisory Committee to advise on policy and to provide technical guidance on tuberculosis, such course being permissible by section 2 (3) of the Act.

(2) For the control and direction of the day-to-day tuberculosis work of diagnosis and treatment each regional board should appoint a tuberculosis committee to be assisted by a regional tuberculosis officer and staff. The committee could take the form of (*a*) selected members of the regional hospital board with coöpted persons of experience in tuberculosis, or (*b*) an advisory technical body of mainly tuberculosis officers and medical officers of health, or (*c*) in large regions, both (*a*) and (*b*)—that is, a tuberculosis committee aided by a technical body.

(3) The tuberculosis medical staff for each region should consist of one or more graded medical *teams* with clerical assistance and tuberculosis health visitors who would assist in the dispensary work and bring a first-hand knowledge of the family circumstances and conditions and contacts—so important in a scheme based on persuasion. Each team could be given responsibility for an area containing several hundred thousand population and preferably coextensive with one or two hospital management committee areas. The teams should perform both dispensary and sanatorium duties, work in the closest relation with the general practitioners, examine contacts, and be given the definite duty to assist the medical officers of health of county and county-borough councils in care work and in preventing the spread of infection. Each team should have a register of all the tuberculosis cases in their area and generally hold the tuberculosis service together so that they would always know what is happening to the patients, both pulmonary and non-pulmonary.

(4) Throughout the country there are many small tuberculosis institutions; it is the intention gradually to eliminate these as separate units and to provide equivalent accommodation as part of the large and improved general hospitals. This may take a long time. Meanwhile how should the day-to-day management of the existing sanatoria be effected? I suggest that they and the tuberculosis dispensaries be taken as a group in each region and administered by the regional tuberculosis committee, who could and should coöperate where advantageous with hospital management committees in the region.

The proposed transfer of the whole hospital and specialist services on April 1, 1948, will involve (along with general medical, dental, pharmaceutical, and ophthalmic services) a considerable feat of organisation. In the event of delay, and if the date fixed cannot be amended, I suggest that the county councils and county boroughs be asked to continue by contract the tuberculosis service on behalf of the regional boards until the transfer can be made on a well-planned basis.

Church Stretton, Salop. G. LISSANT COX.

SAND-FLY FEVER

SIR,—In their article of April 5, Dr. Fleming and his colleagues state that since sand-flies were difficult to find in the Naples area they were not able to confirm their clinical diagnosis. This was not the experience of our American colleagues, who carried out extensive searches and satisfied themselves on this point in both the Naples and Caserta areas.

The high incidence in the summer of 1945 was probably due to the increase in the number of troops billeted in towns and villages which had been damaged in the previous year. It was noted in the Middle East that this illness was more common in Service people living in towns and villages than in troops engaged in active warfare in the open.

From my personal experience, I am sure that the preicteric fever, when it occurs, heralds the onset of jaundice by four or five days at the most, and that during the latter part of this time the earliest gastrointestinal symptoms of nausea and anorexia manifest themselves. In the autumn of 1940 it was quite commonly found that men evacuated from the Western Desert 48 hours previously with a diagnosis of sand-fly fever, and with all the symptoms of this condition, arrived in hospital apyrexial but with an increasing jaundice.

It would be interesting to know whether any of Dr. Fleming's volunteers developed jaundice within 3–4 weeks of the inoculation of the serum of patients with sand-fly fever, because one feels that there may possibly be some similarity between the virus of sand-fly fever and that of infective hepatitis.

Children's Hospital, Birmingham. GEORGE KOMROWER.

SOCIAL PATHOLOGY

SIR,—After reading your admirable leader and Prof. Perrin H. Long's fine factual and philosophical address, many physicians will ponder again and further over the subject of social pathology.

Many will agree that social medicine should be a development in clinical medicine. This is a fundamental idea which should be in the minds of the teachers of medicine, whichever age-group of patients may be their particular concern. The tendency to geographical divorcement of the patients and wards from the realities of the outside world has not been conducive to a complete study of the individual and his environment. It is increasingly apparent, however, that clinical teachers are making headway towards a better synthesis of the factors related to a person's health or sickness. Moreover the added interest to physician, student, and nurse in knowing as fully as possible "what sort of a person is he?" rather than the brief material approach of "what has he got?" gives a warmer climate to one's work and enhances understanding of the all-round treatment required to make a patient better and happier. When a careful, tactful, yet comprehensive survey is made of their way of life, many patients gratefully recognise that something more than mere treatment of their particular disease is being attempted.

One might argue that clinical medicine has always aimed at understanding the "whole man": and of course many practitioners daily practise the principle, even so far as, on occasion, to treat the person rather than the disease. It may well be that the hospital physician has been at a disadvantage in his assessment of a patient, in so far as he seldom possesses detailed knowledge of a patient's home, work, and leisure. In the present better-regulated outpatient departments, which afford more time for inquiry, a full and purposive social history should form an essential part of the clinical approach.

In England Now

A Running Commentary by Peripatetic Correspondents

TOBACCONISTS must be lonely men these days; not that some of them haven't asked for it. I'm disappointed in my chap; on the morning after the Chancellor's fateful speech I found my way to him barred by a closed door: "Back in Ten Minutes," said the notice. But twenty minutes later the door was still locked, and quite a lot of angry customers were trying to lure the wretched fellow out of his hiding-place, where he was presumably counting his excess profits when the prices went up next day. At lunch-time "Back in Ten Minutes" had given way to "Closed All Day for Stocktaking." The next morning it was invitingly "Push," but no-one did.

These are testing days; indeed for those with a mind for the finer things they are critical days. Some of us are moved to philosophy: "Just look," said the man in the station buffet, indicating the unclaimed piles of yellow, blue, and red packets, "just look; in the war we could pay for 'em but couldn't get 'em, and now we can get 'em but can't pay for 'em. It makes you think." It does indeed. But what most of us want to know is how we are to face our plight. Well, of course, you can give up smoking altogether; I did yesterday, but after three hours I modified my ideas along more rational lines. (It was only for a moment that I felt like the drunk who, being taxed with failure to stay on the water-cart, explained: "I just put one foot down to steady myself.") Now I ration myself to a pipe after every meal, plus any additional ones needed to keep my fingers steady enough to hold a pen or lift a knife and fork. Not everyone, I appreciate, is strong enough to stick to such a scheme as this. These weaker brethren could do no better than attend my course for tobacco addicts next week. Naturally patients must on arrival hand over to me all tobacco in their possession; but I attach great importance to keeping these subjects alive to the temptation they will be exposed to on return to the outside world; so they must be prepared to sit and watch me smoke. It's a great idea, really. Success guaranteed, or money back. But not the tobacco. That is expendable by me on the treatment sessions.

* * *

It is a peculiarly irritating phenomenon (irritating is the operative word) that whenever my oldest son's school term starts I get threadworms again. There is no snob association about it; it has happened regularly at his prep. school, private school, nursery school, and council school. (Yes: we *have* moved about a bit.) Nor does there appear to be any sectarian bias; all institutions act in the same way, whether C. of E., R.C., free-for-all, or frankly atheistic. Before he handed it on to me I used to take a detached and tolerant view of the boy's infection—"You can find them in every child if you look long enough"; "Lot of rot about causing general debility"—that sort of thing—but I well recall the shattering experience of discovering at midnight with a pocket mirror, a torch, and a good deal of general contortion that my own pruritus was due to the same invader. The moment when one first discovers oneself to be harbouring a living parasite is disintegrating and humiliating, to say the least. To make matters worse, when I fled to my spouse, who is a hard-hearted pathologist, for comfort and consolation, I was met with laughter and gentian-violet pills. (The trick of swallowing these whole is to keep your tongue glued to the back of your lower teeth.) However, a week later I noticed she wasn't quite so ready to snort when I remarked that there was much to be said for a private tutor, or even a nice governess.

* * *

The other day I heard of someone who was alleged to be able to recite 114 causes of albuminuria. Such a combination of analytical gymnastics and mnemonic virtuosity should appeal to those who recommend the intensive study of Latin in schools "as a mental discipline." But this trifle of knowledge was being looked on as a handy weapon for an approaching grapple with the Censors, so I wondered whether the M.R.C.P. examination was worthy of this implied slight. I was somewhat reassured by the latest papers, which do not seem to favour an approach by preformed "lists of causes." But the membership is a "higher exam."; can we be sure that, in the final M.B. or Conjoint, the man with a music-hall memory will not be at an undue advantage in his finals, compared with the man who thinks of disease in terms of a comparatively small number of physiological mechanisms which can be disturbed in different ways? It is unfortunate that questions of the type "Give the causes and symptoms of . . ." are easier to correct than questions which demand some selection and synthesis on the part of the candidate. Yet our ultimate progress in medical wisdom is largely along the path of selection and synthesis; we learn what diseases are common, and how they are related, while at the same time we preserve our sanity by forgetting a good many of the polysyllabic syndromes which Dame Nature has once or twice been caught scattering from her malign cornucopia of ill health. In natural history, the taxonomic approach is regarded as subsidiary to an understanding of evolutionary trends. Is it not time that we in medicine tried to free ourselves from the crossword-puzzle fascinations of multiplying syndrome; and should not this attitude be reflected in the examination papers set?

* * *

While I was on holiday a patient with sciatica, whom I had been treating (with success) on the assumption that his pain was due to gluteal fibrositis, was examined by a colleague who referred him as a prolapsed disk to a neurosurgeon. The surgeon confirmed this diagnosis, but, considering the man's symptoms to be partly hysterical, refused to operate until the patient had seen a psychiatrist. On my return a nurse told me that the diagnosis had been changed to "introverted disk." Touché!

* * *

There's been a lot of talk lately about choosing people suitable for various careers, especially for medicine. Everyone agrees that intelligence tests alone are not enough. I believe the following additional quotients are necessary, and I await suggestions how to measure them. Taken together with the I.Q. they would give a very fair measurement of personality.

The *Bee-in-bonnet Quotient* (B.I.B.Q.) assesses the prejudice coefficient of a man. A doctor with a high B.I.B.Q. will hold one belief to the exclusion of all others, and will find some diagnosis in his particular specialty to fit every complaint. Nevertheless, his constancy of purpose and unflagging application may bring him success where others have failed. Research-workers should have low B.I.B.Q.'s, or they will discover only what they believe. Reformers should have high B.I.B.Q.'s, lest they get bored with repetition or dismayed by repeated failure. The bee-in-bonnet type of man is liable to be tedious and unpopular in community life, but he is useful because he gets things done.

The *Goat-getting Quotient* (G.G.Q.) is highly important, for it measures the degree to which the candidate gets other people's goats. It depends on thick skinnedness, lack of tact, the possession of irritating personal habits, and so on. Intelligent people surprisingly often have a high G.G.Q., and less able people may be preferable for a post because others can work with them. It isn't always easy to see how these remarkable goat-getting properties arise, but everyone knows the type that though free from major defects manages to rub others up the wrong way.

Then there is the *Goose-booing Quotient* (G.B.Q.), expressing ability to say boo to a goose. This is the inverse of the *Yes-man Coefficient*, which can be expressed as Y.M.C. A high G.B.Q. is an asset to the intelligent but a menace in the hands of a fool, for to have the courage of one's convictions is useless if the convictions are foolish, and leads to senseless aggression. A high G.B.Q. is essential for iconoclasts, deans of medical schools, and chairmen of committees. Those with low G.B.Q.'s are a delight to dictatorial medical superintendents or fierce ward sisters, who find them a pleasure to handle; they also make good housemen for chiefs who make mistakes but do not wish to be corrected.

So there are four headings under which you can jot down impressions of your fellow men: intelligence, bee-in-bonnet, goat-getting, and goose-booing. We already have matrix tests, &c., for intelligence; no doubt psychologists will evolve appropriate methods for measuring the others.

illion of monochloramine in water is tasteless and lourless and does not harm tissues; it is however a ry effective bactericidal agent and completely disrupts e organic molecule that is mainly responsible for the jectionable odour.

St. Margaret's Hospital,
Epping, Essex.

FRANK MARSH.

THE GENERAL PRACTITIONER'S PENSION

SIR,—I was much interested in your reply last week Dr. Gordon Ward's letter. Your suggestion about nus years to compensate for time-lag is an excellent e and has the great merit of being practical.

With regard to provision of "pension or insurance," entioned in your last paragraph, I remember that me years ago, when I was writing *Your Doctor of the uture,* I found that this solution had considerable support medical, legal, and actuarial circles. On the other nd, Major-General Mitchiner, of St. Thomas's Hospital, eaks with authority in saying: "long years on the oyal Medical Benevolent Fund have convinced me at some form of universal contributory scheme is sential."

Superannuation bristles with difficulties, but it does ppear that if the first five and last five years of general practitioner's working life are not reckoned, he average of the remainder (in most cases about 0 years) would give a fair computation.

Worthing, Sussex.

HAROLD LEESON.

DELAYS AT THE TELEPHONE

SIR,—A peripatetic correspondent of April 5 complains hat the general practitioner is commonly kept waiting 0–40 minutes before a houseman at the hospital answers is emergency telephone call. It is unfortunately rue that on occasions G.P.'s are kept waiting a very ng time for a house-officer to be found. But this is, feel, due more to the nature of a hospital than the luggishness of the houseman. The following list of easons why I have kept G.P.'s waiting may help to alm the fury of your correspondent:

(1) I have already been on the telephone.

(2) I have been in the theatre, either scrubbed up or næsthetising.

(3) I have been engaged in some manœuvre such as a ransfusion, lumbar puncture, or paracentesis.

(4) I have been in my bath.

These causes of delay cannot readily be avoided. But here is a fifth cause, in some hospitals, that could e avoided. This is a faulty method of notifying the ouseman that he is wanted. Where coloured lights hich flash all over the hospital are used, one knows t once when one is wanted. But when the telephonist as to phone each ward and department, it is possible o spend nearly an hour "chasing" the house-officer ound the building.

Instead of the house-officer doing six months as a G.P., s your correspondent advocates, I suggest that he should lo a fortnight as a house-officer to remind himself that he resident does not sit at the end of a telephone all ay long. He would also discover that there is a very erious shortage of nurses just now, and there are none tanding "straining at the leash for our commands."

Romford, Essex.

MICHAEL D. WARREN.

CERVICOBRACHIAL SYNDROMES

SIR,—Your annotation of April 12 points out that here is so far no agreement on causal anatomical and ostural factors, and quotes Leriche's remark that a number of these syndromes are still unclassified. Anatomical rrangement and abnormalities of the parts have ttracted more attention than physiological mechanisms, nd the sympathetic supply to the brachial artery has een noted mainly because it is vulnerable, being exposed o pressure or irritation at the level of the first rib or ervical rib. However important these anatomical considerations may be, they do not explain every case in which differences are observed between the brachial and the axillary arteries, the former being contracted and pulseless below the level of pectoralis major insertion, the latter normal above this level.

It is not uncommon to find contraction of the brachial artery in cold-sensitive psychotic patients, who display severe peripheral cyanosis when exposed to mild chilling at room temperatures of 60–64° F; the artery is contracted to a firm pulseless cord which can be rolled under the finger but dilates fully after warming an indifferent limb (reflex vasodilation), whereas the axillary artery can be felt and seen to pulsate normally above this level. Observations on these patients, which will be reported more fully elsewhere, suggest a "physiological" level below pectoralis major insertion, with greater vasomotor alertness below this level, strikingly displayed in some exaggerated thermoregulatory reactions.

F. MACKENZIE SHATTOCK.

Three Counties Hospital, Arlesey, Beds.

PERITONEAL DIALYSIS

SIR,—Mr. Reid and his colleagues (Feb. 15, p. 269) prefer intermittent to continuous irrigation on the ground that the latter may permit sidetracking much of the peritoneal surface by the development of a straight channel between the inlet and outlet tubes. This has never been observed in our necropsy material in patients or in animals, for the apparent reason that irrigation, when uncomplicated by infection, does not provoke deposition of fibrin when heparin is used. In animals dye injected into the inlet tube shortly before death stained the entire peritoneal cavity, even when there was peritoneal inflammation. Peritoneal irrigation continued for many days, with or without peritonitis, shows no decline in the capacity of the peritoneum to clear urea. Nevertheless there may be an advantage in using intermittent irrigation. We also have used this method occasionally, but we have always maintained a current flow instead of a stagnant pool.[1] The latter has the notable advantage of greatly reducing the volume of irrigating fluid required, and we do not doubt its capacity to extract as much of the retention products as does continuous irrigation.

The finding, by Mr. Reid and his colleagues, of a concentration of urea in the fluid in excess of that in the blood requires some elucidation. In 1939 Gilligan and Altschule[2] showed that the thiocyanate levels in blood and a fluid deposit take from four to ten hours to reach equilibrium, depending on the volume of the fluid deposit. In the two-litre volume used by Mr. Reid the urea content of the fluid at its point of contact with the diffusion membrane will be higher in the earlier phase of the diffusion period than towards the end of this period. The average urea content of the fluid after two hours should be the mean of the concentrations in the blood at the beginning and at the end of the period. This mean will be higher (cf. Gilligan and Altschule) than the blood-urea level measured at the end of the period, and lower than that measured at the beginning of the period, assuming that all the fluid with a still higher urea content from a previous rinsing period has been completely extracted. It would be necessary to have all these data before accepting the implications from Mr. Reid's statement.

We agree with Mr. Reid's warning of greater danger from waterlogging than from a moderate hæmoconcentration, because uræmic patients are especially susceptible to pulmonary œdema, which may be rapidly fatal. With the formula variations we have used we have not had reason to fear hæmoconcentration except in one instance, when the fluid used consisted of 5% gelatin solution plus $2^1/_2$% glucose.

Mr. Reid's suggestion that penicillin may be irritating to the peritoneum deserves consideration, but the concentration we have used is less than that in blood when average parenteral therapeutic doses are used. Mr. Reid's further suggestion that exudate may interfere with osmosis does not conform to our observation that in the presence of peritonitis the urea excretion

---

1. In certain instances when the sump did not reach or did not remain in the cul-de-sac, we were not successful in avoiding stagnation. Such a stagnant pool can be the source of unintended overhydration if it remains after ionic equilibrium is reached. The time required for this depends on the fluid volume, but it is surprisingly short. Therefore, it is essential to remove a stagnant pool of fluid before it loses hypertonicity.
2. Gilligan, D. R., Altschule, M. D. *J. clin. Invest.* 1939, 18, 501.

Liaison with the social service has been sadly neglected. In the past year or so it has become increasingly evident that a collateral social history, taken by a skilled person, *will elucidate factors contributing to dyspeptic, rheumatic,* thyrotoxic, and many other disorders. Thus the discovery of occult factors, which seem to raise or lower a person's susceptibilities or which appear to unmask a constitutional trend, can be made. Medical students certainly find this approach interesting and helpful, and it gives an added educational value to their study of the patient. The insidious progression of disorder to disease can often be nicely correlated with the pressing problems in the social history.

Our teaching should not be limited to the clinical and special methods of diagnosing the lesion; we must proceed to inculcate the notion that some of the commoner diseases, such as rheumatoid arthritis and ulcerative colitis, have not uncommonly a preamble in psychosomatic or neurosomatic stresses, which, if fully explored through the channels of clinical and social medicine, may be remedied in such a way and at such a time that progression of the disease is checked. The student should develop an attitude of mind whereby he says to himself, "I know the diagnosis is (say) duodenal ulcer, or asthma; but why has this occurred in this individual? What are the factors, outside ordinary medical or surgical practice, which must be inquired into in order to get the patient back on to a firm and steady track?" By such a clinical discipline the student will come to learn the significance of the possible conflicts of personality and environment in its widest sense: the gradual—or sometimes apparently acute—wearing down of somatic resistance under stress, or, one might say, the decline of one or more of the barometers of health to a degree sufficient to precipitate disease.

Social study of the patient therefore reaches a high plane of practical application, and one can readily see *how futile is the treatment of patients without this* larger background to work upon. It implies an intelligent interest in the family life, the factory, the particular good or bad industrial selection of the individual, the educational and possibly scholastic problems of the child, and a host of variables which may be gathered up to allow a final conclusion in the "total diagnosis." I hope that a better appreciation of all this will be shown by hospital authorities, so that each physician will be able to have his social worker at hand at all times. It *may well be that if social pathology is intensively* studied, we shall gain much information on the causes of the common maladies; in fact, it may be regarded as an important research project in hospital practice. The scheme at Newcastle-upon-Tyne, as outlined by Prof. R. C. Browne, is excellent.

Birmingham. A. V. NEALE.

THE MEDICAL SCHOOL

SIR,—Like "Amos" (March 29), I was a war-time student at one of London's medical schools; but unlike him I have no complaint against the organisation of my teaching. Certainly I have not found teachers indifferent to our presence "and to our early difficulties in approaching the patient in his bed." At my school we had an elementary course in medicine and surgery for six months after taking the 2nd M.B., and during our early clinical training we had lectures on nursing techniques by a sister-tutor.

I would comment on Amos's five suggestions as follows. (1) The average student is not in a position to know what is really good for him. (2) I commonly see in our hospital a round taken by a registrar who is teaching 3 or 4 students individually; larger rounds are split up now that the numbers of men qualified to teach has increased. (3) Our lectures were very systematic, but I agree that teaching in some of the special departments left much to be desired. (4) I cannot see any benefit to be gained from student house appointments: the newly qualified house-officer is quite raw enough. (5) The final suggestion, that students should sit on medical rounds, adds weight to the contention of some of the older teachers that the medical student of today is rapidly becoming more decadent. We willingly stand for three hours to watch a rugger match, yet are supposed to require a chair for a ward round.

HOSEA.

HEALING OF PEPTIC ULCERS

SIR,—I would like to add a few points in support of Dr. Morton Gill's excellent article of March 8.

For a number of years I have been struck by the symptomatic improvement which so often follows immediately upon the initiation of full investigation. Time and again patients referred to me on account of resistance to routine treatment have at the second consultation which follows radiological and pathological investigation reported remarkable lessening of symptoms. It has often been possible to show that symptomatic improvement has gone hand in hand with a *process of healing; and this observation has* been made too frequently to be merely accidental. Nor does it seem likely that the barium meal by its mechanical effect deserves the credit for this happy state, though I have heard this suggestion put forward. It is more probable *that the confidence which full investigation commonly* engenders has been responsible.

We have treated with Young's duodenal tube a number of patients who had large lesser-curve ulcers previously resistant to full hospital treatment. This method has been so immediately successful, and it has apparently mattered so little whether the tube reached the duodenum or remained curled up in the stomach, that it looks as though the effect was more on the psyche than on the soma.

For ten years phenobarbitone has been used freely in the treatment of peptic ulcer, and I am firmly convinced that it is still the most useful drug in the ulcer syndrome. This again emphasises the importance of the patient's emotional state.

Finally, I have sometimes wondered whether the unquestioned success of certain surgical procedures owes something to the effect upon the victim's soul; for there remains amongst us a certain inherent faith in the drama of surgery. It will be interesting to learn whether the cases of perforation which are treated without operation show the same long symptom-free interval which can so confidently be expected to follow surgical closure.

Winchester. KENNETH ROBERTSON.

EX-SERVICE ADMINISTRATORS

SIR,—After ten weary years in the Indian Medical Service may I support the plea of "Burma Star" (Feb. 15) that military administrators should be kept out of the National Health Service. It was a poor commentary on the I.M.S. that from 1942 the consultants in India Command were almost entirely drawn from the home teaching hospitals. Under the guidance and encouragement of these distinguished men the standard of military medicine was raised to a level which has never been achieved by the pure "administrators." The patient had come into his own.

Let us see to it that we start with a clean slate. Let the newborn infant be tended through its first years by men who wish to see it flourish and not by those who will smother it in innumerable forms, the bane of the clinician and the delight of the "administrator." Let us ensure that when the doctor is called to see a case, he is able to think of the patient and that he is not subconsciously worrying about a pair of Spencer-Wells forceps which have disappeared from his surgery.

ENMESHED.

DEODORANTS

SIR,—Your note of April 5, reviewing Mr. Dewey H. Palmer's survey, quotes his opinion that volatile deodorants should not be used in places where food is stored.

Some years ago I was consulted by a company that owned large refrigerating rooms in the Middle East, on how to abolish the "refrigerating odour" that is so noticeable in such establishments. This odour clings to refrigerated meat, butter, and other foods. I advised them to spray out the rooms every day with a watery solution of chloramine (made by mixing ammonia vapour with water containing free chlorine), and this routine (using monochloramine ten parts per million in water sprayed with an ordinary 'Imshi' pump), together with as much cleanliness as was possible in the treatment of floors and shelves and in the handling of bulk foods, successfully dealt with the nuisance. Ten parts per million of monochloramine in water is tasteless and odourless and does not harm tissues; it is however a very effective bactericidal agent and completely disrupts the organic molecule that is mainly responsible for the objectionable odour.

St. Margaret's Hospital,
Epping, Essex.
FRANK MARSH.

THE GENERAL PRACTITIONER'S PENSION

SIR,—I was much interested in your reply last week to Dr. Gordon Ward's letter. Your suggestion about bonus years to compensate for time-lag is an excellent one and has the great merit of being practical.

With regard to provision of "pension or insurance," mentioned in your last paragraph, I remember that some years ago, when I was writing *Your Doctor of the Future*, I found that this solution had considerable support in medical, legal, and actuarial circles. On the other hand, Major-General Mitchiner, of St. Thomas's Hospital, speaks with authority in saying: "long years on the Royal Medical Benevolent Fund have convinced me that some form of universal contributory scheme is essential."

Superannuation bristles with difficulties, but it does appear that if the first five and last five years of a general practitioner's working life are not reckoned, the average of the remainder (in most cases about 40 years) would give a fair computation.

Worthing, Sussex.
HAROLD LEESON.

DELAYS AT THE TELEPHONE

SIR,—A peripatetic correspondent of April 5 complains that the general practitioner is commonly kept waiting 30–40 minutes before a houseman at the hospital answers his emergency telephone call. It is unfortunately true that on occasions G.P.'s are kept waiting a very long time for a house-officer to be found. But this is, I feel, due more to the nature of a hospital than the sluggishness of the houseman. The following list of reasons why I have kept G.P.'s waiting may help to calm the fury of your correspondent:

(1) I have already been on the telephone.

(2) I have been in the theatre, either scrubbed up or anæsthetising.

(3) I have been engaged in some manœuvre such as a transfusion, lumbar puncture, or paracentesis.

(4) I have been in my bath.

These causes of delay cannot readily be avoided. But there is a fifth cause, in some hospitals, that could be avoided. This is a faulty method of notifying the houseman that he is wanted. Where coloured lights which flash all over the hospital are used, one knows at once when one is wanted. But when the telephonist has to phone each ward and department, it is possible to spend nearly an hour "chasing" the house-officer round the building.

Instead of the house-officer doing six months as a G.P., as your correspondent advocates, I suggest that he should do a fortnight as a house-officer to remind himself that the resident does not sit at the end of a telephone all day long. He would also discover that there is a very serious shortage of nurses just now, and there are none standing "straining at the leash for our commands."

Romford, Essex.
MICHAEL D. WARREN.

CERVICOBRACHIAL SYNDROMES

SIR,—Your annotation of April 12 points out that there is so far no agreement on causal anatomical and postural factors, and quotes Leriche's remark that a number of these syndromes are still unclassified. Anatomical arrangement and abnormalities of the parts have attracted more attention than physiological mechanisms, and the sympathetic supply to the brachial artery has been noted mainly because it is vulnerable, being exposed to pressure or irritation at the level of the first rib or cervical rib. However important these anatomical considerations may be, they do not explain every case in which differences are observed between the brachial and the axillary arteries, the former being contracted and pulseless below the level of pectoralis major insertion, the latter normal above this level.

It is not uncommon to find contraction of the brachial artery in cold-sensitive psychotic patients, who display severe peripheral cyanosis when exposed to mild chilling at room temperatures of 60–64° F; the artery is contracted to a firm pulseless cord which can be rolled under the finger but dilates fully after warming an indifferent limb (reflex vasodilation), whereas the axillary artery can be felt and seen to pulsate normally above this level. Observations on these patients, which will be reported more fully elsewhere, suggest a "physiological" level below pectoralis major insertion, with greater vasomotor alertness below this level, strikingly displayed in some exaggerated thermoregulatory reactions.

F. MACKENZIE SHATTOCK.

Three Counties Hospital, Arlesey, Beds.

PERITONEAL DIALYSIS

SIR,—Mr. Reid and his colleagues (Feb. 15, p. 269) prefer intermittent to continuous irrigation on the ground that the latter may permit sidetracking much of the peritoneal surface by the development of a straight channel between the inlet and outlet tubes. This has never been observed in our necropsy material in patients or in animals, for the apparent reason that irrigation, when uncomplicated by infection, does not provoke deposition of fibrin when heparin is used. In animals dye injected into the inlet tube shortly before death stained the entire peritoneal cavity, even when there was peritoneal inflammation. Peritoneal irrigation continued for many days, with or without peritonitis, shows no decline in the capacity of the peritoneum to clear urea. Nevertheless there may be an advantage in using intermittent irrigation. We also have used this method occasionally, but we have always maintained a current flow instead of a stagnant pool.[1] The latter has the notable advantage of greatly reducing the volume of irrigating fluid required, and we do not doubt its capacity to extract as much of the retention products as does continuous irrigation.

The finding, by Mr. Reid and his colleagues, of a concentration of urea in the fluid in excess of that in the blood requires some elucidation. In 1939 Gilligan and Altschule[2] showed that the thiocyanate levels in blood and a fluid deposit take from four to ten hours to reach equilibrium, depending on the volume of the fluid deposit. In the two-litre volume used by Mr. Reid the urea content of the fluid at its point of contact with the diffusion membrane will be higher in the earlier phase of the diffusion period than towards the end of this period. The average urea content of the fluid after two hours should be the mean of the concentrations in the blood at the beginning and at the end of the period. This mean will be higher (cf. Gilligan and Altschule) than the blood-urea level measured at the end of the period, and lower than that measured at the beginning of the period, assuming that all the fluid with a still higher urea content from a previous rinsing period has been completely extracted. It would be necessary to have all these data before accepting the implications from Mr. Reid's statement.

continues to be as high as when the peritoneum is not inflamed.

We have not observed pain from the procedure, or any injury to the viscera from pressure caused by the tubes.

Our view is that control of chemical balance will not be so difficult as control of peritonitis. We have recently modified our method of loading the carboys containing the irrigating fluid so as to reduce the possibility of contamination from this source. We have also modified the outlet tube so that it cannot slide back and forth in the incision, and that overflow of fluid cannot collect in the dressings round the incision. Back flow of such fluid containing skin organisms through or alongside the tube is thus avoided. The air entering the irrigating fluid carboy is now filtered through alkaline cresol and parachlorphenol solution. If these improvements in sterility technique solve the problem of peritonitis, the intestinal origin of peritoneal infection in these patients can be dismissed. If not, this source of contamination will need further exploration. Preliminary studies of this problem are in progress. Meanwhile all patients, except those suspected of sulphonamide sensitivity, receive sulphthalidine by mouth to reduce intestinal bacterial counts.

We have recently modified the irrigation system by combining the inflow and outflow systems in a double-tube arrangement connected to a much shortened and weighted sump drain, the whole of which lies deep in the cul-de-sac and which is introduced so that neither overflow nor backflow can occur. A small volume of a hypertonic fluid is run in and totally removed every 15 minutes with a resulting satisfactory urea clearance. This prevents overhydration and we have reason to believe it will also prevent peritoneal contamination from the skin. The apparatus will be described in a forthcoming publication.

We wish to thank you for the interest you have shown in this problem and the care you are taking to point out its difficulties and complexity, so that the harm done by injudicious use of the method will not overbalance the possible good that may come of it.

HOWARD FRANK
ARNOLD SELIGMAN.

COMPRESSION OF MEDIAN NERVE IN CARPAL TUNNEL

SIR,—I apologise for returning to this subject (*Lancet*, March 8, 22, and 29, April 5), but I must reiterate that the median nerve is normally enlarged and pinkish in colour proximal to the anterior carpal ligament. This pseudoneuroma has been well known for over a hundred years.

Every nerve in the body increases in cross-sectional area before passing beneath a ligament. This increase in area is due to the addition to the nerve of a nutrient artery and vein. Beneath the ligament, on the other hand, the nerve usually receives no arteries or veins and is surrounded by a sheath of loose cellular tissue. Moreover the swollen pinkish nerve, which is circular or slightly elliptical in cross-section proximal to the ligament, becomes definitely flattened beneath the ligament.

The internal popliteal (posterior tibial) nerve is pinkish and swollen proximal to the ankle-joint. Beneath the various ligaments at the ankle the nerve (or its internal and external plantar branches) becomes flattened. This normal " pseudoneuroma " on the posterior tibial nerve is almost as well marked as that normally situated on the median nerve. The external cutaneous nerve of the thigh, as it passes beneath Poupart's inguinal ligament, lies in a sleeve-like sheath of loose cellular tissue.

It has been shown that there is a smaller amount of connective tissue in the female nerve than in the male, and as far back as 1853 Romberg called attention to the fact that neuromata are much less frequent in the female than in the male. Gowers stated that lesions of the median nerve, if rare, are apt to be severe and their course correspondingly prolonged. Kinnier Wilson stated that " weakness and atrophy of the median muscles, partial or complete, sometimes follows prolonged use of trade tools, or constant repetition of professional movements—an ' occupation ' neuritis seen occasionally for example in gardeners, ironers, scrubbers, carpen smiths, dentists, and others, whose business entails th grasping instruments for long periods, or pressing into the ball of the thumb."

When I suggested that the hand should be ligh bound over a solid core in the position of rest I ass that the use of cotton-wool was known, for the har cannot be lightly bound without placing a solid core the palm. There is no risk of compression of the nerve or of its digital or muscular branches with such a dressing intelligently applied.

Anatomy School, University of Cambridge. H. A. HARRIS.

BONES IN THE BANK

SIR,—I had the pleasure of meeting Dr. Bush in New York last November, and I feel sure he would wish to correct an impression given by your annotation of April 12. His interesting work on the storage of bone did not originate in Pennsylvania but in that famous institute of orthopædics, the New York Orthopædic Hospital, where until recently Dr. Bush was on the staff. I saw his bone bank at that hospital, and was convinced that worth-while results were being achieved, in spite of the biological disadvantages which one might expect from previous experience with homogenous skin and nerve grafts—let alone the heterogenous grafts which you mention.

Exeter. NORMAN CAPENER.

THE CALL-UP

SIR,—In your annotation of April 12 you made a strong case for the economical use of newly qualified medical men. You did not, however, discuss the simplification of the problem if the student put in his year's service with the Colours before entering a medical school.

For a certain proportion, this timing would, I think, be advantageous to all concerned. The man who passes straight from school to hospital without a period of general education at a university is especially in my mind. The knowledge of the outside world acquired and the personal contacts involved in any of the Services should equip him better for his medical career than does the average school education.

Most teachers agree that the ex-Servicemen at present training in the medical schools are apt and industrious pupils. Though the comparison is not exact the circumstances are in some degree parallel.

Faversham, Kent. MAX PAGE.

*** We agree with Sir Max Page that the enthusiasm and judgment of the ex-Service medical student strengthen the claim for a break between school and university. Ideally, no doubt, there ought to be a break; but present conditions are far from ideal. We argued on March 22 (p. 375) that the supply of doctors is limited by the number of places in the medical schools, and that a later age of entry is extravagant because it reduces the professional life of those who gain admission. We also suggested that any further delay in qualification is both biologically and professionally undesirable: even now the doctor marries late, and the profession loses good recruits who attach importance to an early marriage and family. When, as is feasible, these drawbacks are removed, there will be nothing against, and much in favour of, an interval before medical training. It should lessen the strain now imposed by continuous book-work between the ages of 7 and 23. —ED. L.

CORRECTION OF MEDICAL REGISTER

SIR,—I am desired by the Returning Officer to say that voting papers for the purpose of the forthcoming election of one member of the General Medical Council to represent the registered medical practitioners resident in England were issued on April 22 to all practitioners having registered addresses in England; and that the authorities of the Council would be glad if any such practitioner who has not received a voting paper would communicate immediately with the office of the Council (44, Hallam Street, London, W.1), *whether or not he proposes to vote in the election*, in order to ascertain that his address is correctly entered in the Medical Register.

MICHAEL HESELTINE
Registrar.

London, W.1.

GROUPING OF HOSPITALS

SIR,—It would be difficult to exaggerate the importance of some of the issues raised in your editorial last week on the grouping of hospitals. It is time that attention was drawn not only to the critical nature of the nursing problem which will confront the regional boards in any case, but also to the additional hazards which will be introduced if the method of grouping ignores the psychological aspects of recruitment and staffing.

An arbitrary pooling and distribution of nursing staff in a region, in accordance with needs but out of accord with personal choice, would inevitably reduce the pool to drought level. The limited measure of direction of nurses into the scarcity fields during the war indicated how violent is the reaction against interference with a nurse's free choice of work, and how harmful such interference can be to the cause of nursing recruitment.

It would be disastrous to group hospitals in such a way that some groups had no focal hospital of strong recruitment appeal and had to depend on staff drafted in by the regional board. Already potential recruits are asking at the Nursing Recruitment Centre, "If I take up nursing, may I choose my own hospital, or shall I come under a scheme which will send me to any hospital?" On the answer to that question may depend the decision to take up nursing or to choose some other career. Instead of reducing the source of supply even further than at present, it would be well to stimulate recruitment by allowing some measure of competition, and then, by a process of natural adjustment, to staff the scarcity fields with a generous overflow from other fields.

Many of the teaching hospitals have doubled the capacity of their preliminary training schools for the time being in order that they may staff additional beds, and have thereby reduced their waiting-lists both of student nurses and eventually of patients. A number of other voluntary hospitals could follow their lead if they had sufficient accommodation for nursing staff.

This is in line with your suggestion of including deficit hospitals in a group containing a teaching hospital or other hospital which is able to increase its intake of nurses. A nurse who has chosen a particular general hospital will gladly work in the chronic wards attached to that hospital when she would resist transfer to an institution for the chronic sick—probably by leaving hospital service altogether.

In a profession already regarded as hemmed about with restrictions, we could not afford to sacrifice the element of free choice of hospital and thereby to widen still further the gap between demand and supply.

H. MORLEY FLETCHER
Chairman, Nursing Recruitment Committee.

Nursing Recruitment Centre, 21, Cavendish
Square, London, W.1.

ANALGESIA IN LABOUR

SIR,—It is now nearly fourteen years since R. J. Minnitt showed that women can be helped in their confinements by the administration of nitrous oxide. Further developments of Minnitt's technique, such as the Chassar Moir attachment, and the promising results with 'Trilene,' now make it possible to promise the expectant mother that her confinement will not be the nightmare of former days. Yet full use is not being made of these recent advances.

During the past few months I have received a number of letters telling the same sorry tale, and, from my own observation, I know that these correspondents have good reason to complain; many hospitals do not seem to recognise that the relief of pain during confinement is a primary duty. Analgesia is too often administered half-heartedly and for too short a time.

The two main reasons for this lamentable failure are (1) lack of medical interest, and (2) shortage of staff. I have found that while the actual administration of the analgesic can be entrusted to nurses, yet there must be "medical interest" in their work. It is essential that an experienced anæsthetist, genuinely interested in the relief of pain in labour, should watch the administration from time to time, and should frequently inspect apparatus; for only a trained anæsthetist can notice at once the small mechanical defects which so frequently lead to bad results.

Are we not asking too much of our overworked midwives? Would it not be much better to have a number of nursing auxiliaries trained as analgesists, with no other duties? We cannot rest content with present arrangements, which are neither to our credit nor to our advantage. In 1937 there was published a Maternal Mortality report, which shook public confidence in our profession. I have little doubt that if a 1947 Maternal Analgesia report were to be published we should suffer an even worse loss of prestige.

New Barnet. JOHN ELAM.

Obituary

SYDNEY ARTHUR MONCKTON COPEMAN

M.D. CAMB., F.R.C.P., F.R.S.

Dr. S. Monckton Copeman was an officer of the Local Government Board and Ministry of Health for over thirty years; but though he became an able administrator he remained an investigator, and it was no accident that in 1898, while the Vaccination Bill was passing through Parliament, Copeman in his Milroy lectures to the Royal College of Physicians was describing the scientific experiments which led to the official adoption of glycerinated lymph.

He was educated at King Edward VI School at Norwich, where his father was a canon, and at Corpus Christi College, Cambridge. In 1885 he qualified from St. Thomas's Hospital, and he took his M.D. five years later. Meanwhile he had served as an assistant lecturer in physiology and morbid histology at St. Thomas's and taken the D.P.H. in 1889 preparatory to joining the Local Government Board in 1891. It was in this year, at the International Congress of Hygiene, that he first called attention to his method for the bacteriological purification and preservation of vaccine lymph. The admixture of glycerin with vaccine lymph was, as he himself pointed out, no new device, but he was the first to recognise its selective action in eliminating extraneous germs from the lymph without affecting the specific virus. Later, with F. R. Blaxall, he showed the advantage of glycerin over soft paraffin and lanolin as a vehicle for vaccine lymph.

Press Portrait Bureau

Copeman remained at the Ministry till 1925, and served not only his own department but also the Home Office and Board of Trade as a Government delegate to European countries and to the United States. His own profession he served as a member of the council of the Royal College of Physicians, as president of the epidemiology section of the Royal Society of Medicine, and as a special commissioner of the British Medical Association. During the 1914–18 war he was in charge of the department of hygiene at the Royal Army Medical College, holding the rank of lieut.-colonel. He was also for many years lecturer in public health at Westminster Hospital, an examiner for the Conjoint Board and for the universities of Bristol and Leeds, and chairman of the board of studies in hygiene of the University of London.

Though working long at a desk he did not lose his interest in the bench. His papers on the relationship between variola and vaccinia were read before the Royal Society in 1903, and in the same year he was elected to their fellowship. He had already been awarded the Cameron prize of the University of Edinburgh, and the Fothergill medal of the Medical Society of London, and he was later to receive the Buchanan gold medal of the Royal Society, the Jenner medal of the Royal Society of Medicine (1925), and the gold medal of the International Faculty of Sciences (1938). His interests were not limited to the subject which he had made his specialty, and with M. Greenwood he wrote a paper on diet and cancer. In 1928, at the International Cancer Congress held in London, he read a paper on irradiated fluorescein in the treatment of cancer, and he was a member of the Ministry of Health's committee on cancer.

On his retirement Copeman continued his public-health work from a different angle as a member of the hospital and medical services committee of the London County Council and as chairman of the public-health committee of Hampstead borough council. He also contributed articles to the *Encyclopædia Britannica* and the *Dictionary of National Biography*. A member of the livery of the Society of Apothecaries, he was a freeman of the City of London, and a knight of grace of the Order of St. John of Jerusalem. "To his juniors," writes a colleague, "he was especially kind and courteous: a generous host, a genial neighbour, he always had the knack of seeming pleased to see one. His wide experience was ever at the disposal of his friends, and anyone who consulted him would receive of it in full measure. I shall always remember gratefully one occasion of great urgency in connexion with an outbreak of anthrax, when Copeman's knowledge and his prompt and effective action saved a dangerous situation, and incidentally greatly relieved me."

Dr. Copeman died at Hove on April 11, at the age of 85. His wife, Ethel Margaret, daughter of Sir William Boord, predeceased him, and they leave two daughters and a son, Dr. W. S. C. Copeman.

KURT LEWIN

The death of Kurt Lewin in Massachussetts in February at the age of 56 deprives the world of science of a vigorous and an integrating mind. He was not a medical man, but like a good clinician he could combine the results of investigations made in a number of fields of inquiry in such a way that each investigation was seen as part of a whole. His chief gift to medicine, however, was an indirect one through his contribution to the philosophy of science.

He began work in the famous Berlin Psychological Institute with a team which created the *Gestalt* school of psychology (Wertheimer, Koffka, Koehler, and others), but when the Nazis were coming into power he emigrated to America. There he absorbed a new aspect of "dynamic psychology" and did much to give the *Gestalt* and the Freudian ways of thought a mutual illumination. He was a professor and trained as a laboratory research-worker, but his laboratory in the latter part of his life was in "real-life situations"; he brought his powers of conceptualisation into everyday life and made the workshop of industry and the classroom his laboratory and tested there his theories "in real life." Appropriately he found a home in the Massachussetts Institute of Technology, and was head of the department of group dynamics. An annotation on his contribution to psychology appears on another page.

Births, Marriages, and Deaths

BIRTHS

Ayres.—On April 17, at Chippenham, the wife of Dr. Geoffrey Ayres—a daughter.

Beckett.—On April 20, in London, the wife of Dr. H. D. Beckett—a son.

Campbell.—On April 16, the wife of Mr. W. G. Campbell, F.R.C.S.—a son.

Currie.—On April 13, in London, the wife of Dr. Donald Currie—a daughter.

Herbert.—On April 16, at Worksop, the wife of Dr. George Herbert—a daughter

MacLeod.—On April 17, in London, the wife of Mr. Cameron MacLeod, F.R.C.S.—a daughter.

Russell.—On April 17, the wife of Mr. P. M. G. Russell, F.R.C.S.—a daughter.

Tait.—On April 11, at Edinburgh, the wife of Dr. G. B. Tait—a son.

MARRIAGES

Charles—Hume.—On April 18, at Newcastle-upon-Tyne, John Alexander Charles, F.R.C.P., to M. F. Hume.

Howat—Harker.—On April 18, at Goathland, Yorks, James M. L. Howat, M.B., to Margaret E Harker, M.R.C.P.

DEATHS

Blackmore.—On April 13, George John Blackmore, M.D. Edin., D.P.H., aged 83

Gill.—On April 17, Cyril Illingworth Carswell Gill, M.B. Camb., aged 53.

Manson.—On April 13, James Kennedy Manson, M.B. Glasg

Orton.—On April 18, George Harrison Orton, M.D. Camb.

Smith.—On April 16, John Morland Smith, M.R.C.S., D.A., aged 32.

Tibbetts.—On April 15, Arthur Willoughby Tibbetts, M.R.C.S., aged 49.

Notes and News

NEWLY QUALIFIED ASSISTANTS

Position in Relation to Military Service

The Central Medical War Committee thinks it desirabl to draw attention to the fact that newly qualified practitioner liable to military service, although now free to accept assistantships in general practice, are not free to remain in suc appointments after they have been qualified for six month

The committee urges all newly qualified practitioners, i their own interests and the interests of the hospitals, to see junior hospital appointments of the A category. A practitioner liable to military service is granted deferment t enable him to hold such a post for six months, *provided that he has obtained the post within three months of qualification* He is then granted a further six months' deferment if selected for a B2 post, and if, on completing this post, he is appointed to a B1 post, his recruitment is again deferred, normally for twelve months at least, and he may eventually be recommended for recruitment as a graded specialist. If, however, he enters general practice on qualification, his recruitment is initiated about five months after the date of qualification with a view to call-up when he has been qualified for six months, and the committee will not then entertain an application for deferment for the purpose of gaining hospital experience before undertaking military service.

At the present time, male practitioners are liable to military service as general-duty medical officers if they were born on or after July 1, 1916.

SUTTON INDUSTRIAL NEUROSIS UNIT

When men and women in industry need psychiatric advice they will normally be referred first to an outpatient clinic The Ministry of Health notes (Circular 64/47) that they may need outpatient treatment, and adjustment of difficulties at home or at work; or will profit by a period in a training centre before resettlement; or that they may be fit to undertake ordinary or sheltered work at once. Some, however, will need inpatient treatment in hospital, and some will be uncoöperative and unemployable. Finally, there are some about whom a decision cannot be reached at the outpatient clinic, and who present a problem to both the clinic and the employment exchange. For these, a special inpatient centre of 100 beds was opened on April 1 at Sutton Emergency Hospital, where they can get psychiatric treatment, occupational assessment, work therapy, and occupational therapy, according to their needs. Work therapy will be carried out in a normal work environment—whether firm, shop, Government training centre, or technical institute The period spent in hospital will be 6–8 weeks, which is not long enough, of course, for a complete training, but which is sufficient to allow the medical staff to study aptitudes and advise on vocational selection.

Applications for admission made either through the Commissioner of Medical Services (in the case of ex-Service or ex-Merchant Navy patients whose accepted war disablement is psychosis or psychoneurosis), or else through a neurosis centre, must be accompanied by a psychiatrist's report Final selection of cases will be made by the hospital authorities at Sutton.

COLOUR-VISION TESTS ON VIEW

The Colour Group of the Physical Society had assembled an instructive collection of apparatus for testing colour vision, as part of the Physical Society's exhibition held in London on April 9–12. Many of the tests mentioned in the Colour Group's report [1] were on view. These ranged from the simpler tests, like the Holmgren wools and the various confusion test charts, to delicate research apparatus, like the Wright colorimeter. The first room contained the simpler classical tests—the Ishihara and other confusion charts, the Holmgren wools and various other matching tests—and also some new apparatus based on the principle of the Nagel Anomaloscope. In this type of test the subject views a circular field divided into two. One half of the field is a standard yellow, while the colour of the other half is determined by the subject who can vary a mixture of red and green. The Shaxby test and one devised in Messrs. Ilford's research department are of this kind. Messrs Kodak have produced a test in which pairs of light filters of different colours are selected to detect the different types of colour-blindness; these filters are illuminated by an ordinary X-ray viewing box and the subject is asked to point out the pairs which match. These new tests are very simple to apply but are designed to give a high degree of sensitivity. The apparatus is not yet generally obtainable.

---

[1] Report on Defective Colour Vision in Industry. See *Lancet*, April 5, p. 455.

Other exhibits included the Board of Trade lantern, which is designed to imitate conditions at sea, and some highly specialised research apparatus which makes it possible to determine the exact nature and degree of a defect of colour vision; in this type of apparatus the source of light is usually a pure spectrum.

At present the materials for many of the classical tests, such as the Ishihara, are very scarce, and they are not easy to produce because the colour of the inks used in printing them is all-important. Any really large-scale testing of sections of the population is therefore ruled out, but experiments on reasonably large samples might now be made to determine which tests could most easily be applied to large numbers without sacrifice of sensitivity.

TESTIMONIALS FOR EX-R.A.F. MEDICAL OFFICERS

To clear up misunderstanding among released medical officers regarding the furnishing of a testimonial, the Director-General of Medical Services, R.A.F., writes: "*A document of this nature, if it is to be of any value, must be written by someone who has a personal knowledge of the individual who requests it, and on this condition senior officers are empowered to give such testimonials. The practice in this Directorate-General is to advise ex-Service doctors who write to us for testimonials to apply to senior officers of the Medical Branch under whom they have worked, for a statement of their character and professional skill. Letters addressed to senior medical officers, care of this Directorate-General, will be forwarded. A released medical officer may obtain a certificate of service based on the whole of his service by applying to the Under-Secretary of State, Air Ministry (A.R.9), Kingsway, London, W.C.2.*"

University of Sheffield

On July 1 the honorary degree of D.SC. will be conferred on Sir Howard Florey, F.R.S.

University of Leeds

On Monday, May 5, at 3.30 P.M., Dr. M. N. Smith-Petersen, professor of orthopædic surgery in Harvard University, is to deliver the Moynihan lecture at the University Union. He is to speak on the Evolution of the Surgery of the Hip-joint.

Royal Faculty of Physicians and Surgeons of Glasgow

The following have been admitted to the fellowship:

James Allan, Richard Thomas Stanley Gunn, John Raven Lauckner, Alasdair Cameron Macdonald, John Hamilton Ramage, David Neilson Ross, qua physician; James Arthur Victor Hamilton, David James Livingstone, Iain McLennan, Valliyaveetil Muhamed, John Neilson, Alexander Paterson, William Reid, David Gemmell Smith, qua surgeon.

Scottish Conjoint Board

The following have been admitted licentiates of the Royal Colleges of Physicians and Surgeons of Edinburgh and the Royal Faculty of Physicians and Surgeons of Glasgow.

M. S. Barnett, H. Y. Caldwell, R. H. Freedman, J. McD. Hanley, W. P. Hanley, Garnet McDermott, Josephine B. McElroy, Hugh McIntyre, R. D. Watssman, E. F. Weiswasser, A. M. Westwater, N. G. P. de S. Wijesekera, Mariella M. Williams.

University College of the West Indies

Mr. B. W. Williams has been appointed medical adviser and dean of the medical school of this college, lately established at Jamaica, which is associated with the University of London.

Mr. Williams, who is 51, was born in Jamaica and educated at Oundle School, and Exeter College, Oxford. During the first world war he served as a trooper in the 2nd King Edward's Horse and later in the Royal Field Artillery reaching the rank of captain. On demobilisation he continued his medical studies at St. Thomas's Hospital; he qualified in 1921, graduated as M.B. two years later, and took his F.R.C.S. in 1924. After holding house-appointments at St. Thomas's he became first assistant in the surgical unit there and was later elected to the staff. He is also surgeon to the Mount Vernon Hospital, Northwood, and consultant surgeon to the L.C.C. hospital service. He has examined for the University of Oxford and the Royal College of Surgeons, and he has held the office of subdean at St. Thomas's. During the late war he served in the R.A.M.C. with the rank of lieut.-colonel. He has published papers on abdominal infections, including his Hunterian lecture of 1927 on toxæmia due to anaerobic organisms in intestinal obstruction and peritonitis.

St. Thomas's Hospital

Prof. W. G. Barnard has been appointed dean of the medical school in succession to the late Prof. B. A. McSwiney.

Guild of Hospital Librarians

A meeting of the guild will be held at Chaucer House, Malet Place, London, W.C.1, at 2.15 P.M., on Wednesday, May 7, when Mr. Adrian Hill will speak on the subject of his book *Art and Illness*.

Central Council for the Care of Cripples

The annual general meeting of the council will be held on Thursday, May 1, at 2.30 P.M. at 1a, Henrietta Place, London, W.1, when Mr. George Tomlinson, Minister of Education, will speak.

Hospitals Day

Hospitals Day in London will be held this year on Tuesday, May 6. Those who wish to help should write to the appeal secretary of their local voluntary hospital or to Lord Luke, chairman, Hospitals Day, 36, Kingsway, London, W.C.2.

British Medical Association

Dr. J. H. Bruce and Dr. John Revans, M.B.E., have been appointed assistant secretaries to the association. Dr. Bruce took his M.B. Glasg. in 1937. Dr. Revans qualified in 1935 from the Middlesex Hospital and afterwards joined the Indian Medical Service.

The London Clinic

Dr. J. D. Robertson has been appointed director of a new department of clinical investigation at the London Clinic. The department, which will include units of hæmatology, biology, histology, and chemical pathology, will provide a comprehensive laboratory service for the clinic and also for outside practitioners.

Society for Relief of Widows and Orphans

At a meeting of the directors held on April 9, with Dr. R. A. Young, the president, in the chair, Dr. E. J. Blackett, who has been secretary for 42 years, tendered his resignation, which was accepted. The annual general meeting will be held on Wednesday, May 21, at 5 P.M., at 11, Chandos Street, London, W.1.

Association of Municipal Medical Officers

This association is being formed, with the knowledge of the Association of Municipal Specialists, to represent the views of medical officers of non-specialist status. Further particulars may be had from the hon. secretary, Dr. J. J. Hamilton, 56, Castlebar Road, Ealing, London, W.5.

Edinburgh Postgraduate Lectures

In connexion with their courses in medicine and surgery the Edinburgh Postgraduate Board is holding the following open lectures on subjects of biological interest: Mr. J. Russell Greig, PH.D., Studies in Comparative Medicine (April 29); Prof. F. A. E. Crew, F.R.S., Biology of Polytocy (May 13); Dr. Reginald Passmore, The Fat of the Land (May 27); Mr. C. P. Stewart, PH.D., Biochemistry of Senescence (June 10); Dr. T. N. MacGregor, Sex Hormones (June 24). The lectures will all take place at 5 P.M. in the west medical lecture theatre of the Royal Infirmary.

Blindness in Africa

The joint mission of the Colonial Office and the National Institute for the Blind which has been inquiring into problems of blindness in British tropical Africa has now returned to this country, and is preparing a report. The mission found that in one small area of Uganda the incidence of blindness among the population was 4187 in 100,000, compared with a rate of 191 in the United Kingdom.

Joyce Green Hospital

On April 21 Mr. A. Reginald Stamp, chairman of the hospitals and medical services committee of the London County Council, opened the extensions completed at a cost of over £130,000 in 1939 when the hospital was converted from an infectious-diseases unit to a general hospital. The new buildings contain wards for neurosurgery and physiotherapy, and for children; clinics for dentistry, for ear, nose, and throat work, and for eyes; an operating-theatre; and a nurses' home. During the war the new wards were not open, because the large amount of glass in their construction made them unsafe.

Appeal for Blood-donors

A number of Post Office stamp cancelling machines are now using dies engraved "Blood donors are still urgently needed." By this it is hoped to assist in the appeal for additional volunteer blood-donors, 200,000 of whom are required immediately.

Closed Shop

Dr. A. T. W. Powell, M.O.H. for Walthamstow, informs us that the council of the borough, having regard to the views expressed by the Ministry of Health, have withdrawn, so far as the medical and nursing services are concerned, their resolution requiring that people in their employ should be members of a trade-union.

Barley Sugar on Prescription

By a Ministry of Food order, which came into force on April 6, glucose barley sugar may be obtained ration free on medical grounds on a doctor's prescription. Not more than 2 lb. may be ordered at a time, but the prescription may direct that this quantity can be repeated twice at intervals of not less than a month.

Gleneagles Fitness Centre

Gleneagles Hotel, taken over in 1939 by the Department of Health for Scotland and used as a hospital and, since 1943, as a fitness centre for the reablement of miners, is being returned to the L.M.S. Railway Company. The centre will reopen at Bridge-of-Earn Hospital, Perthshire, on April 28, where its facilities will be extended by association with the work of a general hospital. Although originally only miners were accepted, any person in industry may now be admitted to the centre if suffering from a disability which may yield to treatment. Patients can be admitted on application to the medical superintendent by their family doctor or the medical officer of a hospital.

U.S.A. Population Increases

The population of the United States is reported by the Census Bureau to have increased by about 10 million since 1940; last July it was 141,288,693, compared with 131,669,275 in April, 1940. Whereas males then outnumbered females by 454,000, females now exceed males by nearly 470,000, this change being attributed chiefly to military losses and the perennial excess of male over female deaths. The numbers have increased in every age-group except 10–19. Shifts in age and sex distribution have been associated with the great rise in the birth-rate dating from the early war years, with reductions in the civilian mortality-rate, and with the small but regular flow of civilian immigrants.

Health Education in Scotland

The Scottish Council for Health Education is holding this summer three schools on the theme of Healthy Living. There will be an elementary course in Edinburgh (July 26 to August 9) under the direction of Prof. James Ritchie; an intermediate course at St. Andrews (in the same fortnight) under the direction of Prof. A. F. Skinner; and an advanced course at Strathpeffer Spa (August 8 to 22) under the direction of Dr. W. G. Clark. Further information may be had from the secretary of the council, 3, Castle Street, Edinburgh, 2. The Central Council for Health Education, Tavistock House, London, W.C.1, is also holding courses at Keble College, Oxford (July 25 to August 8), and at Bede College, Durham (August 20 to Sept. 3).

Recruitment of Midwives

The Secretary of State for Scotland and the Minister of Health have set up a working party to inquire into the recruitment and training of midwives and any other matters which have a bearing on the present shortage of practising midwives. The chairman is Mrs. Mary Stocks, principal of Westfield College, London, and the members are Miss J. P. Forlie, matron-in-charge, Simpson Memorial Maternity Pavilion, Edinburgh Royal Infirmary; Miss V. R. Shand, supervisor of midwives, County of Lancashire; Mr. R. M. Titmuss, of the Cabinet Offices; and Dr. Albertine Winner, of the Ministry of Health. Assisting the working party is a steering committee, also under the chairmanship of Mrs. Stocks, which will include Dr. W. S. Macdonald, of Leeds, and Mr. Arnold Walker, F.R.C.S., chairman of the Central Midwives Board. All correspondence should be addressed to the secretary of the Midwifery Inquiry, Ministry of Health, Whitehall, London, S.W.1.

Return to Practice

The Central Medical War Committee announces that following have resumed civilian practice:

MR. IAN JACKSON, F.R.C.S., M.R.C.O.G., 104, Harley Street, Lond W.1 (Welbeck 1801).

DR. W. ERIC GIBB, 47, Queen Anne Street, London, W.1 (Welb 1011).

Mr. Franklin Kidd, F.R.S., has been appointed director food investigation in the Department of Scientific a Industrial Research.

New arrangements for the issue to ships' surgeons of dri plasma or serum are announced in a Ministry of Transpo notice (no. M. 301); the normal issue for each ship will be bottles.

Appointments

CAMPBELL, RUTH, M.R.C.S.: psychiatrist, child-guidance servic Kent.

CROSBY, J. H. ST.B., M.B. Lpool, D.P.H.: M.O.H., Chingford, and ass county M.O.H., Essex.

LEWSEN, S. C., M.R.C.P.: physician, Institute for Scientific Treat ment of Delinquency, London.

MILNE, ADAM, B.SC., M.B. Aberd.: psychiatrist, Victoria Infirmar Glasgow.

MURDOCH, J. A., L.R.C.P.E.: examining factory surgeon, New castleton, Roxburgh.

SHULMAN, JOHN, M.B. Glasg., D. PHYS. MED.: physician i/c physica medicine, Warneford General Hospital, Leamington Spa.

Napsbury Hospital, Herts:

Chief Physicians:
EDWARDS, A. M., M.B. Lond., D.P.M.
PATTERSON, J. H., M.D. Edin., DIPL. PSYCH.

Diary of the Week

APRIL 27 TO MAY 3

Monday, 28th

ROYAL COLLEGE OF SURGEONS, Lincoln's Inn Fields, W.C.2
5 P.M. Dr. Frankis Evans: Spinal Analgesia.
6.15 P.M. Prof. R. Willis: Pathology of Tumours of the Nose and Throat.

Tuesday, 29th

ROYAL COLLEGE OF SURGEONS
5 P.M. Dr. A. D. Marston: Anæsthesia in Obstetric Practice
6.15 P.M. Mr. J. F. Simpson: Chemotherapy and Antibiosis in Otolaryngology.
EDINBURGH POSTGRADUATE BOARD FOR MEDICINE
5 P.M. (Royal Infirmary.) Mr. J. Russell Greig, PH.D.: Studie in Comparative Medicine.

Wednesday, 30th

ROYAL COLLEGE OF SURGEONS
6.15 P.M. Mr. C. Gill-Carey: Chronic Maxillary and Ethmoidal Sinusitis.
SOCIETY OF HEALTH
2.20 P.M. *Group.* (Civic Hall, Leeds.) Mr. J. Lumsden: Education of Blin Children.

Thursday, 1st

ROYAL SOCIETY OF MEDICINE, 1, Wimpole Street, W.1
8 P.M. *Neurology.* Dr. Erik Lindgren: Normal Temporal Horn and its Deformities by Tumours in the Middle Cerebral Fossa.
ROYAL PHOTOGRAPHIC SOCIETY, 16, Princes Gate, S.W.7
6.30 P.M. *Medical Group.* Mr. Edward Brain: Medical Photography.

Friday, 2nd

ROYAL COLLEGE OF SURGEONS
6.15 P.M. Mr. F. C. W. Capps: Malignant Disease of the Paranasal Sinuses.
ROYAL SOCIETY OF MEDICINE
10.30 A.M. *Otology.* Mr. E. C. Naylor Strong: The Design and Application of Electronic Hearing-aids.
2 P.M. *Surgery.* (Royal Sheffield Infirmary and Hospital.) Operations and demonstration of pathological specimens and X rays.
3 P.M. *Epidemiology and State Medicine.* (Harvard Hospital, Salisbury.) Dr. W. H. Bradley: History of Harvard Hospital and of the Common Cold Research Unit. Dr. C. H. Andrewes, F.R.S.: Plan of Research into the Ætiology of the Common *Cold.* Dr. D. K. M. Chalmers: Routine of Experiments with Human Volunteers. Dr. F. Fulton: Interim Report on the *Results of Transmission* Experiments.
5.30 P.M. *Anæsthetics.* Dr. E. Trier Moerch: Controlled Respiration by means of Automatic Apparatus in use in Denmark and Sweden. Dr. J. Clutton-Brock: Skin *Temperature as a Clinical Aid* during Anæsthesia. Dr. R. P. Shackleton: Anæsthetics in Yugoslavia.

Saturday, 3rd

ROYAL SOCIETY OF MEDICINE
9.30 A.M. *Surgery.* (Royal Sheffield Hospital.) Short papers and clinical cases.

BACKACHE *

B. H. Burns
M.B. Camb., F.R.C.S.
ORTHOPÆDIC SURGEON

R. H. Young
M.B. Camb., F.R.C.S.
ASSISTANT ORTHOPÆDIC SURGEON

ST. GEORGE'S HOSPITAL, LONDON

There used to be no more unwelcome patients in orthopædic departments than those with backache. Now they are much more satisfactory to treat because we know, or think we know, the pathology. Treatment without knowing the pathology is a depressing business.

In our opinion very many of these cases—perhaps the majority—are due to a lesion of the intervertebral disk; in fact, we hold the view that nearly all recurrent attacks of backache, and many cases of chronic backache, are due to disk lesions.

It is impossible to separate backache entirely from sciatica, because both are often manifestations of the same underlying condition. Indeed, it is through the clarification of knowledge of the cause of sciatica that light has been thrown on the cause of backache.

There are two common types of low backache associated with a disk lesion: lumbago and "lame back." Lumbago implies the sudden onset of acute pain in the low back with localised tenderness over the lumbar muscles, or in the mid-line over the interspinous ligaments. The attack may last a few hours or some days. If it lasts more than a fortnight it often passes into sciatica. Examination of movements of the spine reveals restriction of forward bending, whereas sideways bending is free. Between attacks the back may be normal, but there may be some restriction of forward flexion. The patient with "lame back" is often all right if he is lying down, but the pain returns on exercise or even on sitting or standing. It may follow an attack of lumbago, or may be a persistent complaint without acute exacerbations. It sometimes follows a severe and protracted attack of sciatica, in which case, after many months, the severe sciatica subsides, leaving the patient with a chronic backache and occasional pain down the leg.

Both of these types will at some time have restriction of movements, however slight. This will be most notable when the pain is bad.

There is also a type of backache in which there is never any restriction of movement and the only physical sign is tenderness. When the tenderness is localised and constant it may be referred from a visceral lesion; when it is diffuse and variable it may be due to a neurosis.

We shall not discuss those who have discomfort in the back after maintaining an uncomfortable position, such as bending forwards or sitting in an uncomfortable seat. This backache is transient and disappears on altering position. Nor shall we consider the stiffness which follows unwonted activity, for this occurs in all muscles.

We shall try to explain our reasons for thinking that many cases of backache are due to disk lesions. We were slow in coming to this conclusion, for until comparatively recently we had not operated on patients with backache alone, but only when it was accompanied by sciatica. Latterly, however, we have operated in 37 cases for backache alone and found a disk lesion in 34 of them. This number is small, relative to the number of operations for sciatica, because patients with backache alone are seldom bad enough to require operation, and they tend either to get better, or, if they get worse, they usually develop sciatica. Further, most patients with sciatica due to protrusion of a disk have, in their early stages, symptoms of backache only. Of the patients who had their disks removed for sciatica, 68% had pain in the back alone as their earliest symptoms, and the pain was limited to the back for months, or even years, before the sciatica developed.

DIFFERENTIAL DIAGNOSIS

Most of the chronic cases of low back pain not due to disk lesions can be diagnosed by routine radiography, which may show spondylolisthesis, spondylitis (except in the early stages), osteo-arthritis, Paget's disease, old fractures, osteomyelitis, or growths.

Spondylolisthesis is much more commonly recognised than it used to be, largely because of improvements in radiography. Minor degrees with merely a laminar defect require good radiograms and close scrutiny. We have several times operated in such cases, thinking that the patient had a disk lesion. A small apparent slipping may cause a palpable ledge, which may give rise to backache or sciatica, or both.

Spondylitis can be readily detected, for, like any form of arthritis in these joints and elsewhere, it causes restriction of movements in all directions, and is therefore easy to distinguish from a disk lesion, in which sideways movement is free. Except sometimes in the earliest stages it can be confirmed by radiography.

Osteo-arthritis is also revealed by radiography. If it is localised to two adjacent vertebræ it is almost certainly due to an old disk injury. Some patients with severe compression fracture may have persistent pain. The pain is usually felt in the dorsolumbar region—D 11/12 or L 1—and may arise from disalignment of the lateral vertebral joints resulting from the deformity.

Sacro-iliac arthritis is also a rare cause of backache, and in the early stages, before radiological changes have developed, it is difficult to diagnose, but there is often pain on compressing the iliac crests and a positive Trendelenburg sign.

The frequency of *neoplasms* as the cause of low back pain and sciatica has been exaggerated; in the record of 1000 cases of backache kept by one of us (R.H.Y.) some years ago only 6 were due to secondary carcinoma.

Patients with *referred pain* from the visceral organs of the pelvis or the kidneys will have no restriction of movement, though there may be some local tenderness. Gynæcologists agree that intrapelvic conditions are much less often the cause of backache than was formerly suspected; for instance, a retroverted uterus, if otherwise normal, is not now considered to be a cause of backache. Moreover, those intrapelvic conditions which give rise to backache can be readily discovered on examination by a gynæcologist.

In our opinion the incidence of many other conditions which have been accused of causing backache has been unduly emphasised. More than one authority has given support to some of these. True, like us, they regard most conditions as having mechanical, as opposed to infective, causes, but the mechanical causes they give are somewhat different from ours. They make their diagnosis according to the site of the tenderness. When it is over the sacro-iliac joint they call it sacro-iliac strain and recommend manipulation; when it is over the lumbosacral articulation in the mid-line they call it lumbosacral strain and recommend removal of the spinous process. When the patient indicates the site of the pain as being over the lumbar part of the erector spinæ, with muscle spasm, they say it may often be a disk lesion, and that it may improve with physical treatment. Another site of the pain is over the sciatic notch, and they say this may ultimately give rise to a full-blown sciatica, which, in their opinion, is most often due to a narrowing of the lateral vertebral foramen. We hold that the pathology cannot be defined from the site of the tenderness, since patients with proved disk lesions cured by operation have shown tenderness in any or all of these areas.

The explanation of the fact that tenderness is sometimes at a higher level than the affected disk is that, in a disk lesion, the pain in the early stages is, we think, due to tension of the posterior longitudinal ligament, which is stretched over the posterior surface of the disk. It has been shown that the posterior surface of the disk may be innervated by small nerves coming from two or three segments higher, and the pain and tenderness are due to localised muscle spasm induced by irritation of the segmental nerve. We have had many patients who have started with pain, say, over the erector spinæ opposite the third lumbar vertebra, but they subsequently developed sciatica from a disk lesion at the L4–L5 or the L5–S1 space.

---

* Read to the Chelsea Clinical Society on Nov. 12, 1946.

The tenderness at all these various sites may be temporarily relieved by injection of procaine, as was shown by Kelgren some years ago, but one is not justified in implying, as he did, that the pain originates at these sites. The tender areas, as has been shown by Elliott (1944) and confirmed by Weddell et al. (1944) using electromyography, are due to localised muscle spasm arising from an irritation of the nerve-root before it leaves the spinal column.

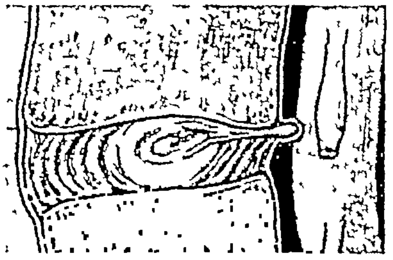

Fig. 1—A small protrusion of the nucleus pulposus through a horizontal tear of the annulus. This gives rise to backache only.

A friend of ours illustrates these points very well.

Many years ago, for pain in her back, she had her sacro-iliac joint fused, but the pain persisted and she was kept on her back for six months. Some time after this, probably because of the rest, she was free from pain. Then we saw her with a tender spot on the upper and outer side of the calf, and we rather lightheartedly diagnosed this as tennis leg, because it came on during a game of tennis. Later, however, she developed a full-blown sciatica. *At laminectomy a large disk lesion was found, the removal of which cured her.*

The moral of this case is that it is misleading to make a diagnosis merely from the site of the tenderness, which is often referred from an intraspinal cause.

ÆTIOLOGY

Persistent backache sometimes follows an injury to the bone or soft parts of the back, as with a chronic sprain elsewhere, but one must not exaggerate the frequency of this condition. Other sites in the body, say in the thigh or arm, which should be equally exposed to strain, are only rarely accused of being the cause of the trouble. We used to diagnose a sprain of the wrist much more often before we learnt to recognise the fractured scaphoid. Once a torn muscle or a flake fracture has become painless elsewhere in the body it remains painless *and is not the cause of recurrent attacks.* An example of this type of fracture is a fracture of the transverse process of a lumbar vertebra. *This will be rapidly and permanently cured if free movement is restored by exercise.*

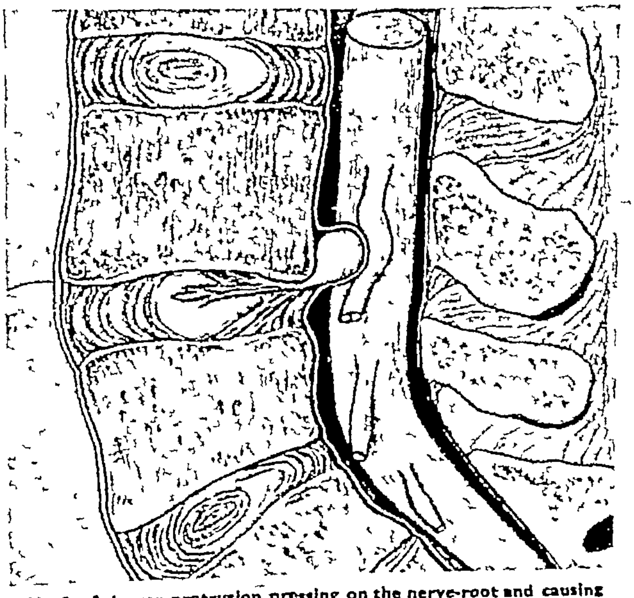

Fig. 2—A larger protrusion pressing on the nerve-root and causing sciatica.

Postural strain may be a factor in some cases of backache. Much emphasis was laid on it some years ago, but we very rarely see this, except in a patient with lordosis below a kyphosis, or perhaps where there is a gross cause for it, as sometimes in the later stages of pregnancy. It should be, and in our experience is, relieved by lying down. *Certainly it is very rarely a factor in the young adult,* in whom it causes only transient trouble.

Postpregnancy backache is said to follow relaxation of the ligaments at parturition, but in a large number of radiograms observed by Roberts (1938-39) the separation of the symphyses was rarely more than 2 mm. Thus it is difficult to see how the sacro-iliac joint could be strained. Postpregnancy backache usually clears up, but where it persists we should expect it to be due to an injury to the disk. In fact, we have had many cases in which a disk protrusion was found and the original injury undoubtedly occurred at parturition.

Sacro-iliac strain from any cause is rare, in our opinion, if indeed it occurs at all.

We regard neurosis as a much less common cause of pain in the back than we formerly did. There is nearly always an organic basis, and it is striking how many patients have been accused of having a neurosis in whom we have found a prolapsed disk. Many cases of what used to be called "railway spine" fall in this category.

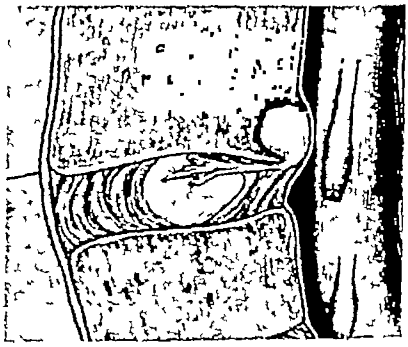

Fig. 3—A condition sometimes found in old-standing cases where the patient no longer complains of sciatica but has persistent backache.

Infective or metabolic causes of backache, such as are attributed to rheumatism or fibrositis, if they exist at all, are not now diagnosed by us. Yet some patients seem to prefer that their recurrent attacks of backache should be ascribed to these causes, rather than to a more precise and accurate mechanical cause. For instance, a patient seems more ready to believe that his attacks of lumbago are consequent on a mild debauch, such as drinking too much champagne or port, than that it should be due to a simple thing like a disk. This is surprising, because it implies, *we should have thought, a considerable constitutional upset,* with a breakdown of the normal metabolism.

We see little evidence of rheumatism, which is supposed to be associated with, or made worse by, cold and damp, *as a cause of painful backaches.* The importance attached to cold and damp as factors in backache or so-called rheumatic complaints has rapidly decreased with increasing knowledge. In the Army the symptoms were often ascribed to these conditions, whereas the truth was that the soldier was at the same time doing strenuous work in which he was likely to damage his disk.

An investigation into "tank back" at a tank-testing unit near Botley revealed that 20% of tank drivers there had backache which came on after they had been driving tanks at speed over rough ground. Those whose age was over 28 or 29 showed a much higher incidence even than this. These patients showed a typical picture of a protruded disk.

In fact, it is becoming increasingly probable that most cases of pain in the limbs have a mechanical cause, and when the pain is referred down the limb *it is due to pressure on the nerve-root.* This applies not only to pain in the lower limb but also to brachialgia or brachial neuritis, many cases of which are due to cervical disk or costoclavicular compression.

PATHOLOGY

We believe it is possible to correlate the symptoms with the pathology we have observed.

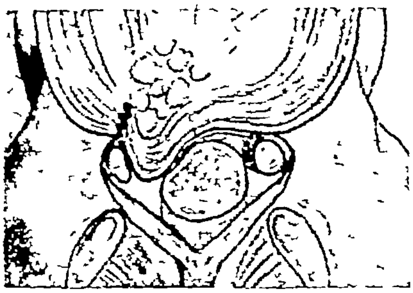

Fig. 4—A tear of the annulus with a bulge.

Fig. 1 indicates how a small protrusion of nuclear material, not large enough to irritate the nerve-root and cause sciatica (fig. 2), can, by causing tension of the posterior longitudinal ligament, give rise to backache alone. These protrusions may pop in and out almost as easily as a hernia does. We have, at operation, often pushed them back; and, if the patient is under light enough anæsthesia to cough or heave, the protrusion reappears.

A similar effect is produced by another type of tear—a lesion of the annulus fibrosus (figs. 4 and 5). Here the torn piece of annulus can swing in and out, mimicking a torn cartilage of the knee. Both these types of lesion, when the protrusion is reduced, give rise to no symptoms, but bending or lifting may force the disk material backwards, producing tension on the posterior longitudinal ligament, thereby causing backache. This, in our opinion, is the explanation of recurrent attacks of backache.

Fig. 3 illustrates an occasional finding in old-standing cases of persistent backache.

TREATMENT AND RESULTS

If these observations on the pathology are accepted, a rational treatment is possible. Needless to say, we do not find it necessary to operate on a high proportion of patients with backache alone. As previously mentioned, most of them get sciatica when they get worse. Nevertheless, operation offers the best chance of permanent cure. None of our patients has been made worse by operation; in fact the operation is without danger—but not without difficulty. The amount of pain and disability have to be balanced against the inconvenience of, and the time spent recovering from, the operation.

The alternatives are rest in bed, or modified rest by wearing a corset. We see little advantage in wearing a plaster cast, since it is more cumbersome and less comfortable than a corset, which is as efficient in restricting movements at the lumbosacral junction.

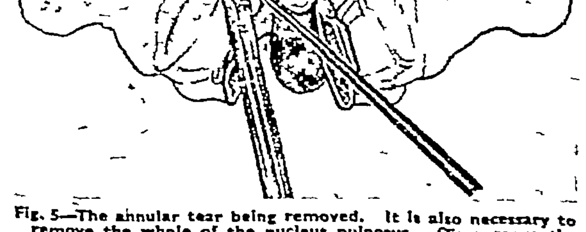

Fig. 5—The annular tear being removed. It is also necessary to remove the whole of the nucleus pulposus. (To remove the charge from the shell, as it were.)

A patient who has an occasional attack of lumbago or a mild chronic backache will prefer to put up with it than submit to operation. Even with sciatica, in the first attack we try the effect of three weeks in bed; then, if the pain goes, we let them off with a caution and a corset. Other types of treatment in our hands have a limited effect, at best only transient. Most of them are efficient in temporarily relieving spasm; but, when the treatment is over, the pain is likely to return. Local injections act in this way, and their effect lasts only a few hours. We have had an extensive experience of epidural injections; they may have been occasionally helpful, probably by anæsthetising the posterior longitudinal ligament or the nerve sheath, but the results are often disappointing and impermanent.

Other forms of physical treatment, such as radiant heat, diathermy, and infra-red rays, do give temporary ease by diminishing the muscle spasm, but their effect is not lasting.

We used to practise manipulation for low backache. Here also the effect was disappointing in our hands, and we rarely do it now. Sometimes it was dramatically effective, probably because it allowed the protruded part to return to its proper place, or shifted the root off the protruded disk. But not infrequently the patient was made worse, and sometimes the patient with sciatica will say that he only had backache before the manipulation, but after it he developed sciatica.

PATIENTS WITH SCIATICA

Treatment	Total cases	Still in pain or having attacks	Symptom-less
Not operated on: First seen 1939–42. Followed up 1945	248	79%	21%
Operated on: 1941–45. Followed up 1946	310	Improved 11% No better 9% } 20%	80%

At one time we used to give all these treatments, and their lack of lasting effect in backache and sciatica is indicated by the accompanying table. Admittedly, this refers to the more severe cases, but the same should apply to less severe cases when the cause is the same.

The figures in the table are from cases of backache and sciatica treated by all the methods in vogue before we operated on them; 248 of these were available for follow-up last year. It will be seen that 79% were still having attacks. Since we began operating in such cases in 1941 the position has been reversed: 80% are now symptomless, and 20% have some pain, 11% being improved but not cured, and 9% no better. All but 9 patients with severe sciatica have been operated on.

The commonest cause of failure, in our opinion, is protrusion of another disk. This occurs less often since we realised that about 12% of the patients operated on have a protrusion of two disks—a double lesion. Another cause of failure, also less common now, is a further protrusion of the same disk, due to incomplete removal of the nucleus pulposus. Re-exploration will remedy both these errors.

A less common cause of failure is a persistently adherent nerve-root. This is benefited by a spinal graft, as are some other uncommon conditions. In fact it is difficult to think of many conditions causing severe low back pain where the pain cannot as a rule be relieved by operation of some description—in a disk lesion removal of the protrusion, in some other conditions by spinal graft, or when there is pressure on the dura or nerve-roots (as sometimes in osteoarthritis or Paget's disease) by laminectomy and uncapping the nerve-roots. Even the pain from a malignant growth of the spine may often be relieved by removing the pressure.

SUMMARY

Persistent or recurrent low backache commonly arises from a lesion of an intervertebral disk or the annulus fibrosus. The other causes can nearly always be diagnosed by straight radiography.

When disk lesions get worse the patient usually develops sciatica.

Operation is the rational treatment for all cases of severe backache due to disk lesions and will cure nearly every case. The operation is free from danger, so the inconveniences of operation must be balanced against those of the backache.

In cases not severe enough to justify operation, all other treatments have a limited effect, except rest and time, which will cure some of them.

Of 310 cases of sciatica due to disk lesions operated on in 1941–45, a follow-up has shown that 80% are still symptomless.

STREPTOMYCIN IN EXPERIMENTAL PLAGUE

DENIS HERBERT *
M.A., Ph.D. Camb.
From the Microbiological Research Department, Experimental Station, Porton, Wilts.

STREPTOMYCIN is an antibacterial substance produced by the mould *Actinomyces griseus.*[29] It has been isolated in a pure state,[4 21 26] and its chemical constitution partly elucidated; it appears to be the meso-1, 3-diguanidino-2, 3, 4, 6-tetrahydroxycyclohexane glycoside of an as yet incompletely identified disaccharide, one hexose component of which is N-methyl-*l*(-) glucosamine.[3 5 22 27]

In the test-tube streptomycin shows strong antibacterial activity against many species of gram-positive, gram-negative, and acid-fast bacteria.[28 29 30 37] It is comparatively non-toxic to experimental animals [12 28] and humans.[13 18 39] These facts suggest that streptomycin may prove a valuable chemo-therapeutic agent, and it has been used to treat various experimental infections in animals with in most cases considerable success.[2 6 7 8 14 15 16 20 23 28 32 38] Preliminary results in small-scale trials on human patients have been rather encouraging.[9 11 17 19]

In particular, streptomycin has given exceedingly good results in the treatment of tularæmia, both experimentally in animals and in man.[11 14] In view of the close biological relationship between *Brucella tularensis* and *Pasteurella pestis* it was decided to test the effect of streptomycin in experimental plague infections in mice and guineapigs.

METHODS

Media.—The medium used for broth cultures was a 2% tryptic digest of casein, pH 7·6, containing 1% sodium glycerophosphate as buffer, and 0·2% glucose ("TC-glucose broth"). For solid media, a tryptic digest of beef muscle, pH 7·6, containing 1·5% agar and 5% of a peptic digest of sheep's blood [10] was used ("TM-PSB agar").

Viable counts were made by delivering from a calibrated dropping-pipette 7 drops (0·2 ml.) of a suitably diluted bacterial suspension on to the surface of TM-PSB agar plates, and spreading the drops by rotation.[24] Colonies were counted after 40 hr. at 37°C. If desired, 1/500,000 crystal violet may be added to the agar to reduce contaminants. The presence of the peptic blood is essential to obtain full development of isolated colonies under aerobic conditions.[31]

Dilutions were made in 0·9% NaCl or 1% phosphate buffer pH 7·6; broth is not superior to these simple diluents.

Opacities of bacterial suspensions were measured in a Hilger Spekker photo-electric absorptiometer and are expressed as optical densities (log I_0/I per cm. depth).

Strains.—The three virulent strains used (nos 327, 336, and 337) were isolated from human cases in North Africa in 1942. Two avirulent strains—Soemedang and Tjiwidej (Otten's vaccine strains [35])—were also used in in-vitro experiments. Stocks were preserved by drying in gelatin-ascorbic-acid broth,[35] by which means virulence has been fully preserved since 1942; cultures in current use were grown in TM-PSB agar stabs and kept at 0°C, subcultures being made monthly for not more than 6 months.

Test Animals.—White mice (18–20 g.) and guineapigs (225–250 g.) were used. To prevent cross-infection, mice were kept in metal boxes with separate compartments for each animal, and guineapigs in separate cages with cloth covers. Animals were examined daily for a minimum of 3 weeks, some for as long as 6 weeks. Most of those dying were examined post mortem, and the spleen and heart blood examined microscopically and culturally for the plague bacillus. A proportion of survivors was also killed at the end of the experiment and examined post mortem.

Infecting Dose.—Cultures grown for 16 hours at 37°C, either in TC-glucose broth or on TM-PSB agar slopes, were used; contrary to Sokhey's [33] findings, they were equally virulent. The standard infecting dose was 0·2 ml of a 1/10[6] dilution of a suspension of optical density 0·2; dilutions may be made in broth, buffer, or saline. This contained on the average about 500 viable organisms; the exact number was determined in each experiment by viable counts.

Streptomycin.—Two batches of streptomycin hydrochloride (Merck) were used; their potencies were 130 and 280 units/mg.—i.e., 16% and 35% pure. (The material was received in January, 1945; much purer preparations are now available.) Solutions of the desired strength were made in normal saline and sterilised by seitz filtration. Doses of 0·2 ml. were injected subcutaneously or intraperitoneally; care was taken to keep the site of injection of the drug as far as possible from the site of injection of the organisms. In most experiments the streptomycin was injected twice daily, in two equal doses morning and evening.

RESULTS

In-vitro Experiments

Streptomycin inhibits the growth of *Past. pestis* in TC-glucose broth (table I). The minimum concentration required for complete inhibition of growth increases somewhat with increasing size of inoculum, but the effect is small, except with very heavy inocula. The apparently diminished efficacy in this case may be due to the more rapid onset of fermentation and consequent fall of pH, since streptomycin is less effective at an acid pH.[1] Tests were made in glucose broth as being a better approximation to in-vivo conditions than plain broth, and because *Past. pestis* grows poorly in plain broth.

TABLE I—INHIBITORY EFFECT OF STREPTOMYCIN ON GROWTH OF STRAIN 337 IN BROTH, SHOWING EFFECT OF SIZE OF INOCULUM

Inoculum (viable cells/ml.)	*Streptomycin concentration (units/ml.)*					
	0	0·5	1·0	2·0	4·0	6·0
$1{\cdot}25\times10^7$	++++	++++	++++	++++	+++	0
$1{\cdot}25\times10^6$	++++	++++	++++	+	0	0
$1{\cdot}25\times10^5$	++++	++++	+++	0	0	0
$1{\cdot}25\times10^4$	++++	++++	++	0	0	0
$1{\cdot}25\times10^3$	++++	++++	+	0	0	0
$1{\cdot}25\times10^2$	++++	+++±	0	0	0	0

Growth from 16-hour TMA-PSB slope washed off, diluted, and inoculated into 10 ml. tubes of TC-glucose broth containing indicated amounts of streptomycin; inoculum size determined by viable count. ++++, +++, &c., indicates extent of growth after 48 hours' incubation at 37°C.

For comparison, the growth-inhibiting effects of sulphanilamide, sulphathiazole, and penicillin were tested under the same conditions (table II). From these results, *Past. pestis* appears considerably more sensitive to all three drugs in vitro than most gram-negative bacteria are reported to be.

The minimum inhibitory concentration of each of these drugs, and of streptomycin, was the same for all the plague strains tested; no difference was observed between the virulent and avirulent strains.

TABLE II—IN-VITRO ANTIBACTERIAL EFFECT OF PENICILLIN AND SULPHONAMIDES

Penicillin	Conc. (units/ml.)	0	0 5	1 0	1 5	2·0	3·0	4·0
	Growth (48 hr.)	++++	+++±	+++	++	+	0	0
Sulphanilamide	Conc. (*M*)	0	$2{\cdot}5 \times 10^{-4}$	5×10^{-4}	10^{-3}	2×10^{-3}	5×10^{-3}	10^{-2}
	Growth (48 hr.)	++++	++++	+++	+	0	0	0
Sulphathiazole	Conc. (*M*)	0	10^{-5}	3×10^{-5}	10^{-4}	3×10^{-4}	10^{-3}	3×10^{-3}
	Growth (48 hr.)	++++	++	+	0	0	0	0
Sulphathiazole and *p*-aminobenzoic acid	Conc. (*M*)	0	10^{-4}	10^{-4}	10^{-4}	10^{-4}	10^{-4}	10^{-4}
	Conc. (*M*)	0	10^{-5}	3×10^{-6}	10^{-6}	3×10^{-7}	10^{-7}	0
	Growth (48 hr.)	++++	++++	++++	++±	±	0	0

Methods exactly as in table I. Strain 337 used in last experiment, and Tjiwidej in first three; inoculum in all cases 6×10^{-8} cells/ml.

Streptomycin appears to have a direct killing action on bacteria, as table III shows. With a concentration of 10 units/ml., an inoculum of 2×10^{6} viable cells/ml. was reduced to 1520/ml. in 2 hours and completely sterilised in $5^1/_2$ hours. With 3 units/ml. the bactericidal action was somewhat slower, but effectively complete in 24 hours, and with 1 unit/ml. no fall in viable count was observed, but growth was delayed compared with the control.

Streptomycin therefore appears to have a bactericidal rather than a bacteriostatic action, in this respect resembling penicillin rather than the sulphonamides.

TABLE III—BACTERICIDAL EFFECT OF STREPTOMYCIN

Streptomycin conc. (units/ml.)	Viable count (cells/ml.) after incubation for:				
	0 hour	0 5 hour	2·0 hours	5·5 hours	24 hours
0	1,900,000	2,600,000	6,500,000	35,000,000	290,000,000
1·0	1,900,000	2,400,000	5,500,000	17,000,000	130,000,000
3·0	1,900,000	2,100,000	2,300,000	970	45
10 0	1,900,000	2,050,000	1520	0	0

10 ml. tubes of TO-glucose broth, containing different concentrations of streptomycin, inoculated with 0 05 ml. of a 16-hour broth culture of strain 337. Samples withdrawn for viable counts immediately and after different periods of incubation at 37°C.

Experiments on Mice

In chemotherapeutic experiments it is important to use a susceptible test animal and a highly virulent infecting organism in sufficient dosage to ensure an almost certain 100% kill in control animals. Strain 337 was used for all the animal experiments reported here. In a typical titration of this strain, subcutaneous doses of 5, 50, and 504 viable organisms killed respectively 19/20, 20/20, and 20/20 mice (mean death times 6·1, 4·8, and 3·7 days). The standard infecting dose was 500 viable organisms; in these and other experiments, in which over 300 control mice were infected with this dose, none survived.

Fig. 1 shows an experiment in which groups of 20 mice, infected subcutaneously with the standard infecting dose, were treated with streptomycin at three different dosage levels. Five doses were given over a 48-hour period, the first dose immediately after infection. At dosage levels of 800 and 400 units/day, the survival-rates were 85% and 45%; all the control mice died. A dosage of 200 units/day saved only 5%, though survival-time was significantly prolonged.

TABLE IV—MICE INFECTED SUBCUTANEOUSLY AND TREATED WITH STREPTOMYCIN 800 UNITS/DAY, STARTED 0, 1, 2, AND 3 DAYS AFTER INFECTION

Streptomycin treatment started:	Survivors (21 days)	Mean death time (days)
Immediately after infection	17/20 (*85%*)	6·8
24 hr. after infection ..	12/20 (*60%*)	8·1
48 hr. after infection ..	1/20 (5%)	5 8
72 hr. after infection ..	0/20	6 0
Controls (no treatment) ..	0/20	3·8

Mice 16–18 g. Infecting dose 349 viable organisms subcutaneous (in back). Streptomycin doses of 400 units in 0 2 ml saline injected intraperitoneally twice daily for $2^1/_2$ days (5 doses = 2000 units in all).

These results show that streptomycin in doses of 800 units/day gives very good protection when used semi-prophylactically—i.e., treatment starting at the same time as infection. A more realistic and more stringent test of the efficacy of a drug is provided by therapeutic treatment. Table IV shows the results of an experiment in which the administration of streptomycin was delayed for 1, 2, and 3 days after infection; in all cases the dosage was 800 units/day (given in two equal doses) continued for $2^1/_2$ days. When treatment was begun at the time of infection 85% survived (cf. the previous experiment); when it was delayed for 24, 48, and 72 hours the survival-rates were 60%, 5%, and 0%. In the last two groups survival-time was significantly prolonged.

Fig. 2 shows a similar experiment in which twice the above dosage of streptomycin was used (1600 units/day) and treatment continued for $3^1/_2$ days. In this case the survival-rates for treatments started 0, 24, and 48 hours after infection were 90%, 95%, and 35%, compared with 85%, 60%, and 5% in the previous experiment. The combination of higher dosage and longer treatment is therefore definitely more effective. There were again no survivors in the group where treatment was delayed for 3 days after infection, though survival was significantly prolonged; it should be pointed out, however, that in this group 30% of the animals were already dead and most of the rest extremely ill before treatment started.

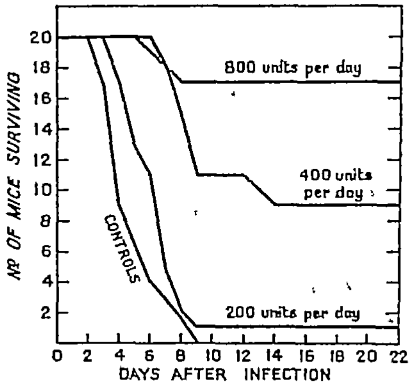

Fig. 1—Effect of different dosages of streptomycin on survival of mice weighing 18-20 g. infected subcutaneously with 592 viable organisms; streptomycin given in doses of 400, 200, or 100 units intraperitoneally twice daily for $2^1/_2$ days (5 doses in all), starting immediately after infection.

At the end of this experiment the survivors were reinfected with the same dose of virulent plague organisms, to test for immunity (table V). In the group whose treatment had been started at the time of infection there was no detectable immunity. In the groups whose treatment started 1 and 2 days after infection there was respectively moderate immunity (26% survivors) and good immunity (86% survivors). The longer the organism is allowed to develop in the body before treatment begins, therefore, the greater the subsequent immunity in surviving animals.

In the experiments so far described the streptomycin was administered in relatively small doses over several days. In view of the bactericidal action of streptomycin in vitro, which is greater the higher the concentration (table II), it was thought that a single massive dose would possibly be more effective than the same total amount of drug given in several small doses over a longer period. Table VI records an experiment in which groups of mice were given a single dose of 2000 units at 0, 24, and 48 hours after infection. The corresponding survival-rates were 80%, 10%, and 0%. In the experiment recorded in table IV the same amount of streptomycin was given in 5 doses of 400 units during $2^1/_2$ days, and here the corresponding survival-rates were 85%, 60%, and 5%; this treatment therefore seems more effective than does administration of all the drug in a single large dose.

In the next experiment streptomycin was compared with penicillin and sulphathiazole, both of which inhibit the growth of the plague bacillus in vitro (table II). Sulphathiazole has already been found to give quite good results in plague infections of mice and men[34 36]; so far as I am aware, no reports on penicillin treatment of plague have yet appeared.

TABLE V—MICE INFECTED SUBCUTANEOUSLY AND TREATED WITH STREPTOMYCIN 1600 UNITS/DAY, STARTED 0, 1, 2, AND 3 DAYS AFTER INFECTION; SURVIVORS TESTED FOR IMMUNITY

—	First infecting dose—1st day (590 viable organisms)		Second infecting dose—24th day (726 viable organisms)	
Streptomycin treatment started:	Survivors *(24 days)*	Mean death *time* (days)	Survivors (21 days *after* 2nd infection)	Mean death *time* (days)
Immediately after infection	18/20 (*90%*)	14	0/18	3 8
24 hr. after infection	19/20 (*95%*)	3	3/19 (*26%*)	5·0
48 hr. after infection	7/20 (*35%*)	9·8	6/7 (*86%*)	12 0
72 hr. after infection	0/20	5·0	..	..
Controls (no treatment)	*0/20*	3·5	..	..
"	..	..	0/20	3·1

Streptomycin doses of 800 units in 0 2 ml. saline injected intraperitoneally twice daily for $3^1/_2$ days; 7 doses = 5600 units (cf. fig. 2). After 24 days, survivors given second infecting dose (but no further streptomycin treatment) to test for immunity.

The minimal amounts of these three drugs required to inhibit the growth of strain 337 in vitro are about 2 units of streptomycin, 3 units of penicillin, and 5 μg. of sulphathiazole per ml. of broth. Groups of infected mice were therefore given each day two doses each sufficient to produce ten times these concentrations in the bodies of 20 g. mice—i.e., total daily doses of 800 units of streptomycin, 1200 units of penicillin, and 20 mg. of sulphathiazole. Two more groups were given 5000 units/day of penicillin and 10 mg./day of sulphathiazole. Treatment was started immediately after infection and continued $2^1/_2$ days with streptomycin and 6 days with the other two drugs. The results are shown in fig. 3.

In the streptomycin-treated group there were 90% survivors, whereas in the penicillin-treated group receiving 1200 units/day there were no survivors (though life was significantly prolonged). Since the doses of the two drugs were in the ratio of their respective in-vitro activities, it is evident that penicillin is relatively much less effective in vivo than streptomycin. One reason for this may be that penicillin is more rapidly excreted. That penicillin has some in-vivo activity is shown by the fate of the group receiving 5000 units/day, in which there were 30% survivors; in view of the relatively enormous dosage, however, this result cannot be considered very impressive.

TABLE VI—MICE INFECTED SUBCUTANEOUSLY AND TREATED WITH SINGLE LARGE DOSE OF STREPTOMYCIN

Streptomycin (2000 units) injected:	Survivors (21 days)	Mean death time (days)
Immediately after infection ..	8/10	6 0
24 hr. after infection	1/10	5·3
48 hr. after infection	0/10	5·5
Controls (no treatment)	0/10	3 6

Infecting dose 592 viable organisms, subcutaneous, in right flank. Streptomycin dose 2000 units in 0 2 ml. saline, subcutaneous, in left flank.

With sulphathiazole (20 mg./day) there were no deaths during the treatment period, but animals began to die after the drug was discontinued, and on the 24th day only 55% survived. This is in contrast to the results obtained with streptomycin, where very late deaths are uncommon, and is in agreement with the view that the action of sulphathiazole is bacteriostatic only, whereas that of streptomycin is mainly bactericidal. Sulphathiazole in smaller dosage (10mg./day) was far less effective, giving only 5% survival, though again most of the deaths were late.

These and other results I have obtained with sulphathiazole are less impressive than those of Sokhey and Dikshit,[34] who used a less severe infecting dose and sulphathiazole doses of 40 mg. and even 80 mg./day, continued for 10 days. In common with other workers, I have found such doses definitely toxic, causing significant death-rates in control mice; 20 mg./day appeared to be the highest safe dose for continued administration.

Better results might have been obtained with sulphathiazole if treatment had been continued longer than 6 days. Even so, streptomycin was considerably more effective with a still shorter treatment period ($2^1/_2$ days) and a dosage well below the toxic level. From these comparative tests streptomycin appears to be definitely superior to sulphathiazole and greatly superior to penicillin.

Experiments with Guineapigs

Guineapigs are as susceptible as mice to plague, though rather less regular in their response; occasional "escapes" may occur with high infecting doses. In a titration of strain 337 in guineapigs doses of 360, 36, and 4 viable organisms killed respectively 7/8, 8/8, and 8/8 animals in 3 weeks (mean death times 6·9, 7·8, and 9 0

TABLE VII—GUINEAPIGS INFECTED SUBCUTANEOUSLY AND STREPTOMYCIN TREATMENT STARTED 0, 1, AND 2 DAYS AFTER INFECTION; SURVIVORS TESTED FOR IMMUNITY

—	First infecting dose—1st day (456 viable organisms)		Second infecting dose—22nd day (693 viable organisms)	
Streptomycin treatment started:	Survivors (22 days)	Mean death time (days)	Survivors (21 days after 2nd infection)	Mean death time (days)
Immediately after infection.	8/8	..	0/8	6 1
24 hr. after infection ..	8/8	..	1/8	7 5
48 hr. after infection ..	8/8	..	2/8	9 5
Controls (no treatment)	0/8	7 1	..	..
"	..	..	0/8	6 5

First infecting dose injected subcutaneously into right flank. Streptomycin doses of 5000 units in 0·5 ml saline injected subcutaneously into left flank, twice daily for $3^1/_2$ days (7 doses = 35,000 units in all), starting at the times indicated After 22 days, survivors given a second infecting dose (but no streptomycin), to test for immunity.

days). The standard infecting dose of about 500 organisms, however, almost invariably produced 100% deaths.

Owing to the scarcity of streptomycin and the larger doses required, it was possible to perform only one experiment with guineapigs, the results of which are shown in table VII. The streptomycin dosage was 10,000 units/day, given in two equal doses; this is the same dosage on a body-weight basis (40,000 units/kg./day) as was used in most of the mouse experiments. Dosage was started 0, 1, and 2 days after infection and continued for $3^1/_2$ days. The results were spectacular; all the treated animals survived 3 weeks, whereas all controls died in 10 days. The treated animals remained healthy and put on weight.

On the 22nd day all survivors and a fresh group of controls were reinfected to test for immunity. The group whose streptomycin treatment had started immediately after infection showed no immunity; all died in about the same time as the controls. In the groups whose treatment had started 1 and 2 days after infection there was some slight evidence of immunity; 1/8 and 2/8 respectively survived, and death times were prolonged. The immunity, however, was much less than in the corresponding experiment with mice (table V).

DISCUSSION

Owing to the scarcity of streptomycin in April-August, 1945, when this work was carried out, many desirable experiments had to be left undone. Incomplete as the results are, they nevertheless show that streptomycin is strikingly effective in the treatment of plague infections in guineapigs and mice. Infection by subcutaneous inoculation produces in these animals a reasonably close replica of natural bubonic plague in man. Intraperitoneal inoculation leads to a more acute type of infection, corresponding rather to pure septicæmic plague. In both types of infection streptomycin appears to be equally effective (cf. figs. 2 and 3).

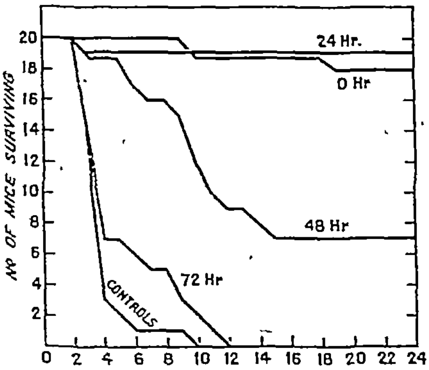

Fig. 2—Effect of streptomycin, 800 units intraperitoneally twice daily for $3^1/_2$ days, on survival of mice weighing 18-20 g. Infected subcutaneously with 590 organisms; treatment started at times after infection indicated on curves.

It has also been possible to produce in animals, by inhalation, lung infections closely corresponding to pneumonic plague in man. (This was done by exposing animals to aerosols of virulent plague organisms produced in an apparatus designed at the Microbiological Research Department, Porton, by Dr. D. W. Henderson, a description of which is shortly to be published.) In this type of infection, also, streptomycin is highly effective—a striking finding, since pneumonic plague is a more severe disease than the bubonic form, with a case-mortality under natural conditions usually close to 100%.

A remarkable feature of streptomycin therapy is the success achieved with comparatively short periods of treatment, or even with a single dose. This is in sharp contrast to sulphathiazole, which has to be given over a long period to produce good results, and suggests that streptomycin has a direct bactericidal action in vivo as in vitro.

The short treatments and moderate doses necessitated in these experiments by lack of material were almost certainly not optimal. For example, mice dying late after short-period streptomycin treatment usually showed local necrotic lesions at the site of infection which were much larger than in control mice (presumably because these died sooner). It seems probable that the streptomycin was preventing any generalised infection but did not succeed in sterilising these necrotic areas owing to inefficient penetration or less effective action at the lowered pH in such lesions.[1] Better results in such cases might well be obtained with larger doses, giving higher tissue concentrations, and with longer periods of treatment. The doses used in these experiments were well below the toxic level.

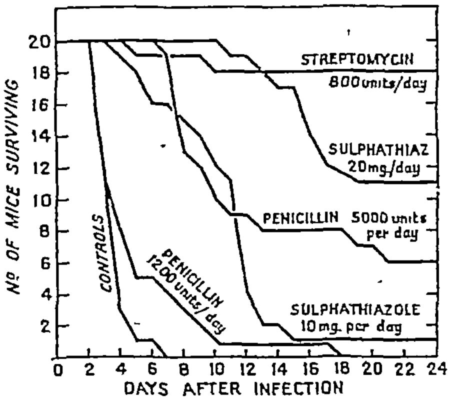

Fig. 3—Comparison of effects of streptomycin, sulphathiazole, and penicillin on survival of mice weighing 18-20 g. Infected intraperitoneally with 599 organisms; drugs injected subcutaneously twice daily, streptomycin being continued for $2^1/_2$ days, and penicillin and sulphathiazole for 6 days.

The guineapigs and mice used in this work are animals with little or no natural resistance to plague. In a species, like man, with a fair degree of natural resistance, even better results might be expected. Now that streptomycin is beginning to be obtainable in reasonable quantity it seems desirable that it should soon be tried in human plague.

SUMMARY

Streptomycin inhibits the growth of the plague bacillus in vitro and, in concentrations of 3 units/ml. or over, brings about rapid sterilisation of plague cultures.

In mice infected subcutaneously with a highly virulent plague strain, in dosage sufficient to kill 100% of control animals, $2^1/_2$-day courses of streptomycin injections (800 units/day) started 0, 24, and 48 hours after infection gave 85%, 60%, and 5% survival. A dosage of 1600 units/day for $3^1/_2$ days gave 90%, 95%, and 35% survival when started 0, 24, and 48 hours after infection.

In guineapigs infected by subcutaneous injection, $3^1/_2$-day courses of streptomycin injections (40,000 units/kg./day) gave 100% survival, even when dosage was delayed for 48 hours after infection.

Streptomycin is equally effective in the treatment of artificially induced pneumonic plague in both mice and guineapigs.

Penicillin and sulphathiazole also inhibit the growth of *Past. pestis*, which in vitro appears more sensitive than most gram-negative organisms to these drugs. In comparative tests in infected mice, however, streptomycin was considerably more effective than sulphathiazole, and penicillin was only slightly effective, even in very high dosage.

This work was done at the Microbiological Research Department, Experimental Station, Porton, where I was seconded by the Medical Research Council. I wish to thank the Chief Superintendent and staff of the department for the help and facilities afforded; the Director, Camp Detrick, U.S.A., for

a generous supply of streptomycin; and the Chief Scientist, Ministry of Supply, and the Medical Research Council, for permission to publish.

CLICKING PNEUMOTHORAX

A. P. THOMSON

M.C., M.D. Birm., F.R.C.P.

PHYSICIAN, UNITED HOSPITALS, BIRMINGHAM

FOR several years it has been known that a patient with a small pneumothorax on the left side may be conscious of a curious clicking sound synchronous with the heart beat, and occasionally this is the only clinical evidence of the condition. Physical examination may reveal nothing of significance, though with the stethoscope the sound is generally to be heard on the left side of the chest in various situations and most often near the apex-beat. Sometimes the "click" is so loud that it is audible at some distance from the chest. Careful radiography may show the small pneumothorax, but its demonstration is not easy.

Scadding and Wood [1] discussed the causation of these systolic clicks due to left-sided pneumothorax. The lesion in the lung is presumably small—e.g., a minute perforation of an emphysematous bulla—and the escape of air into the pleural cavity limited, so that a bubble forms, at the periphery of which there will be viscous adhesion between the visceral and parietal layers of pleura. Should this occur on the left side, each beat of the heart causes a slight separation of the viscous adhesion, with a clicking sound audible to the patient, either because the heart changes its position in systole and diastole, and so alters the shape of the bubble, or as the result of a slight change in intrapleural tension induced by the sudden expulsion of about 100 c.cm. of blood from the thorax in systole. However that may be, there is no doubt that the sound is always synchronous with the heart beat and that it immediately disappears if the pneumothorax increases in size. Scadding and Wood produced the sound experimentally by inducing a very small pneumothorax in a case of tuberculosis; it ceased as soon as a larger quantity of air was injected.

I have records of two patients in whom the small bubble was demonstrated radiographically in the axillary region; neither suffered any pain. Within a few days both developed a total pneumothorax, and the clicking sound ceased. Both of these patients recovered completely; they were under 30 years of age.

All the patients agree that the sound varies in intensity with their position, and that it may in certain postures entirely disappear—possibly because the bubble changes its situation.

CASE-RECORDS

Case 1.—On July 17, 1937, a man, aged 72, was playing tennis, when he suddenly gave a cry and fell to the ground; his breathing became distressed, and he quickly died.

His previous health had been good; he had just returned from a holiday, and his friends had been pleased by his apparent recovery from his wife's death in March of the same year. He had not consulted his doctor, and his sudden end was attributed to coronary occlusion; no necropsy was made.

In 1945, eight years after his death, a journal of his was discovered which contained an admirable description of the essential symptom of limited spontaneous left-sided pneumothorax:—

"*June 11, 1937:* this strange ticking is getting rather more frequent. I cannot locate it except to say that it is not in the heart, nor apparently in the brain. The throat seems the nearest spot that I can suggest—or perhaps over the back of the roof of my mouth. It resembles the tick of a grandfather clock more than any other sound I can identify. It seems to be constantly with me; but, though it seems almost incessant when I am quiet, occasionally it ceases.

"I can give no explanation whatever for its appearance or disappearance. I am in perfect health so far as I know. I suffer from no headaches, no unusual shortness of breath, nor any form of pain or inconvenience, neither is there any thumping or palpitation. It seems better when I am lying on my back in bed; but when I lie on my side it seems much as when I am sitting or standing.

"The first occasion I noticed it was about a week ago. I was alone in the library, and the noise was so loud that I thought it was the kitchen clock ticking, and I went to the door of the kitchen to see if it was open.

"*June 20* (Scilly): up to yesterday there seemed to be little change, but I do not think the noise lasted so long. But last night and today I think it is decidedly better. If, as I imagine, it is nerves, no doubt the perfect rest and holiday are doing it good."

Four weeks later he died suddenly as I have described—almost certainly because the pneumothorax recurred and overwhelmed him.

An important feature of this condition which has not received adequate attention is an occasional severe pain persisting for several days and suggesting on superficial analysis the pain of coronary occlusion.

Case 2.—In 1939 a young man consulted me. Six months previously, while playing tennis, he had been seized with severe pain in the left pectoral region, radiating to the shoulder and down the left arm. The pain persisted for several days and gradually disappeared.

His doctor told him that he had probably had "a clot in the blood-vessel of his heart." He rested for four months and then, as he felt quite well, began to play tennis again without his doctor's knowledge.

A week before I saw him, in the middle of a game, he was seized with similar pain. His doctor rebuked him and referred him to a cardiologist, who confirmed the tentative diagnosis of coronary occlusion and advised complete rest for a year.

The electrocardiogram and radiogram of the heart were normal. Physical examination revealed nothing of importance, and the blood-pressure was 120–80. When I asked him if he had had any other symptom but the pain, he said that he hardly liked to mention it, but on each occasion he had been conscious of a clicking sound, which ceased in the first attack just before the pain disappeared. The sound varied in intensity, and he could make it go by lying on his left side with the trunk slightly raised. I asked why he was diffident about describing so remarkable an experience, and he replied that, when he had done so previously, he had been considered fanciful, and one doctor asked if he had *seen* anything as well, as if he had been drinking.

---

[1] Scadding, J. G., Wood, P. *Lancet*, 1939, ii, 1208.

The same day Dr. James Brailsford demonstrated radiographically a small bubble of air in the upper mediastinal area of the left pleural cavity, and later published the picture.[2] Ordinary anteroposterior and lateral radiograms did not show this bubble, and it took much careful positioning to obtain the radiographic evidence. The man recovered quickly and has led a full and active life since.

Case 3.—In October, 1936, a doctor, aged 32, developed a severe cold; he had no fever, but some rales were found at the right base, and his sputum was a little bloodstained. No tubercle bacilli were found in it, and cultures showed pneumococci. He appeared to recover and went for a holiday.

Six weeks later, soon after returning to work, a sudden pain came on in the left side of the chest and shot down the left arm. The pain in the arm seemed to throb with the heart beat and was worse on effort. He had no cough, no fever, and no dyspnœa. He remained in bed and, while lying on his back, was conscious of a strange rhythmical sound—" like fish falling on a slab "—but he had not noticed, until I pointed it out, that it was synchronous with the heart beat. At the left lateral border of the manubrium in the first intercostal space a sound suggesting pericardial friction was audible with the stethoscope. A radiogram of the chest three weeks after the onset was normal.

The patient has been well since, but in 1938 there was another slight hæmoptysis when he had a cold. Further radiography and several examinations of the sputum revealed nothing.

He probably has a small bronchiectasis associated with an emphysematous bulla which ruptured. In view of the situation of the friction sound the limited pneumothorax was probably in the mediastinal area; as in case 2. An air bubble in this situation might cause pain suggesting angina by its distribution but not by its character, whereas an air bubble elsewhere is painless.

DISCUSSION

Altogether, including the cases described above, I have notes of 8 patients with " clicking " spontaneous pneumothorax; in 2 the condition was associated with pain suggesting angina (1 of these had two distinct attacks in six months); in 5 the sound was detectable with a stethoscope, but in 2 I could hear nothing abnormal, though the patients complained of the clicking, and radiography showed the small pneumothorax. One patient (case 1) was not examined, but his diary leaves no doubt of the diagnosis; 3 patients developed total pneumothorax within a short time of the first appearance of the sound, which then ceased immediately. One man, aged 72, died suddenly about six weeks after the clicks first appeared; total pneumothorax in the elderly is often rapidly fatal.

I agree with Scadding and Wood [1] that the clicking sound in limited left-sided pneumothorax is quite distinct from the crackling to be heard in mediastinal emphysema. In the only case of spontaneous mediastinal emphysema that I have seen—associated with asthma, as it generally is—the sounds were quite different in quality from that of the clicks, and they also varied more with the respiration than with the heart beat.

SUMMARY

A description is given of 3 cases of clicking spontaneous pneumothorax, and 5 others are briefly reviewed.

The clicking is usually heard on the left side, near the apex-beat. It is probably due to an air bubble in contact with a pleural adhesion. Such a bubble can sometimes be demonstrated radiographically.

HYPOPITUITARISM, HYPOGONADISM, AND ANÆMIA

TREATED WITH TESTOSTERONE

GEOFFREY WATKINSON

GEOFFREY EVANS
M.D. Camb., F.R.C.P.
PHYSICIAN, ST. BARTHOLOMEW'S HOSPITAL

THE rôle of the pituitary in hæmopoiesis is well recognised, polycythæmia being associated with basophilism, and anæmia with hypopituitarism. In 1937 Snapper and colleagues first described pituitary deficiency complicated by anæmia, usually macrocytic but in some cases microcytic and hypochromic. Most of the patients had achlorhydria and signs of hypogonadism, and 3 developed subacute degeneration of the spinal cord. All responded well to iron or liver. Witts (1942) reported 2 more cases in which the macrocytic anæmia responded well to liver.

The 2 cases of hypopituitarism and hypogonadism described here are unusual in that the associated anæmia was resistant to treatment with liver, thyroid, or iron but responded dramatically to injections of testosterone propionate.

Case 1.—An engineer's assistant, aged 20, was admitted to the Worcester Royal Infirmary on March 8, 1943, under the care of Dr. H. C. Rook, for increasing lassitude and weakness. At the age of 16 he had had a macrocytic anæmia which responded to liver. Treatment was discontinued at the age of 18.

The most notable feature was his extremely youthful appearance, for he resembled a boy of 13. He was well proportioned but of small stature, with a smooth skin and fine hair. Weight 84 lb. Moderate pallor, with symmetrical pigmentation over the " butterfly area " of the face. He had no axillary hair and had never shaved. Pubic hair scanty but of male distribution. Penis and testicles rather small. He spoke quietly with the voice of an adolescent. Tongue smooth, but had never been sore. Fingers tended to be clubbed; no koilonychia; nails not brittle. Spleen and lymph-nodes impalpable, but liver enlarged to three fingerbreadths below costal margin.

He ran an irregular fever, which reached on occasions 102°F, but produced no subjective symptoms; and in spite of his lassitude and weakness it was with difficulty that he could be persuaded to leave his work and enter hospital for investigation. Thyroid not enlarged. Pulse-rate 80 per min., blood-pressure 120/70 mm. Hg. No signs of disease of central nervous system. Breasts not enlarged. Blood-count showed moderate macrocytic anæmia, with slight or moderate anisocytosis and poikilocytosis; Hb 44% (Haldane), red cells 1,750,000 per c.mm., colour-index 1·25, mean corpuscular diameter 8·6 μ; leucocytes 4100 per c.mm. of which 2173 were neutrophils (myelocytes 41, young forms 41, band forms 41, and segmented 2050), no eosinophils, 41 basophils, 1681 lymphocytes, 164 monocytes, and 41 erythroblasts. There was an associated thrombocytopenia, the platelet count being 45,000 per c.mm.

Sternal puncture showed slightly reduced cellularity, with a decrease in the myeloid-erythroid ratio due to an absolute reduction of the more mature neutrophil leucocytes. Earlier myeloid cells were present in normal proportions. A slight excess of eosinophils was noted and attributed to the liver therapy. A study of the erythroid cells showed a decided erythroblastic transformation, the defect in maturation of the nucleus being more notable than the premature hæmoglobinisation. Megakaryocytes not seen. The findings therefore were those of a dyshæmopoietic macrocytic anæmia not inconsistent with a diagnosis of addisonian anæmia.

Erythrocyte fragility: hæmolysis began at 0·45% and was complete at 0·3%. Test-meal showed achlorhydria, but histamine was not administered. Glucose-tolerance was increased, blood-sugar levels being 54, 55, 58, 64, and 65 mg. per 100 c.cm. Liver function, as assessed by Takata-Ara test and lævulose-tolerance curve, appeared normal. Microscopical examination of the stool showed no abnormality, and no evidence of steatorrhœa was present on chemical analysis of a stool (total fat 35·9%, of which 97% was split). Wassermann and Meinicke reactions negative, and radiograms of pituitary fossa normal. Basal metabolic rate + 32%.

Plasma-bilirubin level 0·2 mg. per 100 c.cm., blood-chlorides 453 mg. per 100 c.cm., serum-potassium 23 mg. per 100 c.cm., and serum-sodium 326 mg. per 100 c.cm. No urinary abnormalities. Urinary androgen output 3 mg. a day. This estimation was performed by the method of Callow et al. (1938), slightly modified by Mr. H. S. Salt. By this method the normal androgen output estimated as 17-ketosterone is 3·5–15 mg. a day in men and 1·7–12·6 mg. in women. The figure therefore was below normal and was additional evidence of hypogonadism.

During the next six weeks various parenteral and oral liver preparations were administered with no improvement. Three blood-transfusions gave only transient benefit. In fact, the hæmoglobin had fallen as low as 28% and red cells to 1,200,000 per c.mm. some four weeks after admission. In this period he lost 5 lb. in weight.

At the end of six weeks, on the advice of Prof. L. J. Witts, the liver therapy was suspended for four days and then started again. In this period testosterone propionate 5 mg. daily was given for two days, and thereafter in doses of 25 mg. twice weekly. The drug produced a rapid improvement in the blood condition. The reticulocyte count rose to 16·5% on the ninth day. The Hb value and red-cell count rose steadily in the next five weeks, Hb reaching 100% and red cells 4,500,000. During the same period his weight increased by 35 lb., and he developed a ruddy complexion reminiscent of the "brewers' drayman" facies. The tongue was thought to be less smooth than previously, and the liver was no longer palpable.

He was discharged after some eleven weeks in hospital and has been seen several times since. Though he has received neither testosterone nor liver, he has remained well and at work, and his blood-count is still satisfactory. He has, however, lost his ruddy complexion, and the vigour and alertness which he possessed while in hospital.

After recovery several of the tests were repeated. A glucose-tolerance test now gave figures of 89, 106, 119, 94, 92, and 90 mg. per 100 c.cm., suggesting that pituitary function had improved. This was further confirmed by the reappearance of free acid in the gastric juice. Mr. Salt investigated the blood-sugar response following the injection of three minims of adrenaline. The result indicated substantially normal glycogenolytic activity:

	Mg. per 100 c.cm.		Mg. per 100 c.cm.
Fasting	97	25 min.	116
5 min.	88	30 ,, ...	104
10 ,, ...	88	40 ,, ...	96
15 ,, ...	96	50 ,, ...	101
20 ,, ...	95	60 ,, ...	106

The relevant features of the case are summarised in fig. 1.

Case 2.—A male clerk, aged 52, was admitted to hospital under the care of Dr. Geoffrey Evans on Feb. 11, 1944, for undue fatigue and impotence. He said that he had never felt well since the last war, when he was discharged from the Army because he was "pale and lifeless." He suffered from severe recurrent colds which completely incapacitated him for several weeks at a time. He was admitted to hospital in 1924 with severe pyorrhœa requiring the removal of several teeth. This was followed by septicæmia, from which he made "a miraculous recovery." After this illness his previous lassitude increased.

He married in 1931 and, though libido was present, he failed to have sexual intercourse on several occasions. He noted that his testicles were becoming smaller, and during the next ten years he experienced no sexual desire. In 1934 he was told he was anæmic and was treated with iron and thyroid. He had been under constant medical treatment since then, and his doctor had found it impossible to raise the Hb level above 70% despite various iron and liver preparations.

For the past year he had noted that the hair on his head was being shed. The hair on his body had almost disappeared. For the past five years he had needed to shave only every third day. There had been no glossitis, dysphagia, or sore corners of the mouth, and no paræsthesiæ had been felt in the extremities.

His height was 6 ft. 2 in. and his weight 13 st. 7 lb. He was coöperative, with a happy disposition, and spoke in a high-pitched rather feminine voice. His skin was pale and sallow, resembling parchment. There was a tendency to prognathism. Hair scanty on the chin and upper lip, thin and fine on scalp. His fat was of the female distribution, as was also his scanty pubic hair. No axillary or pectoral hair was present. There was no gynæcomastia. Mucosæ pale and nails ridged and brittle. Tongue rough, thyroid normal. Heart showed no abnormality; blood-pressure 136/74 mm. Hg; pulse-rate 64 per min. Penis normal in size, but both testicles atrophic, being the size of peas.

He had a moderate microcytic hypochromic anæmia: Hb 62%, red cells 3,250,000 per c.mm., colour-index 0·9; anisocytosis and moderate poikilocytosis present; white cells 8600 per c.mm. (differential count normal).

Test-meal showed histamine-fast achlorhydria. Glucose-tolerance curve showed a moderately increased tolerance (70, 100, 95, 90, and 80 mg. per 100 c.cm.). Basal metabolic rate – 10%.

Sternal puncture (Dr. George Discombe) revealed some marrow hypoplasia, but normoblastic erythropoiesis was present. Gastroscopy (G. W.) showed some atrophy of mucosa in upper half of stomach. Pituitary fossa of normal size on radiography.

Hypopituitarism and anæmia were diagnosed, and treatment attempted with dilute hydrochloric acid and iron. There was no improvement in the blood picture, and the addition of liver

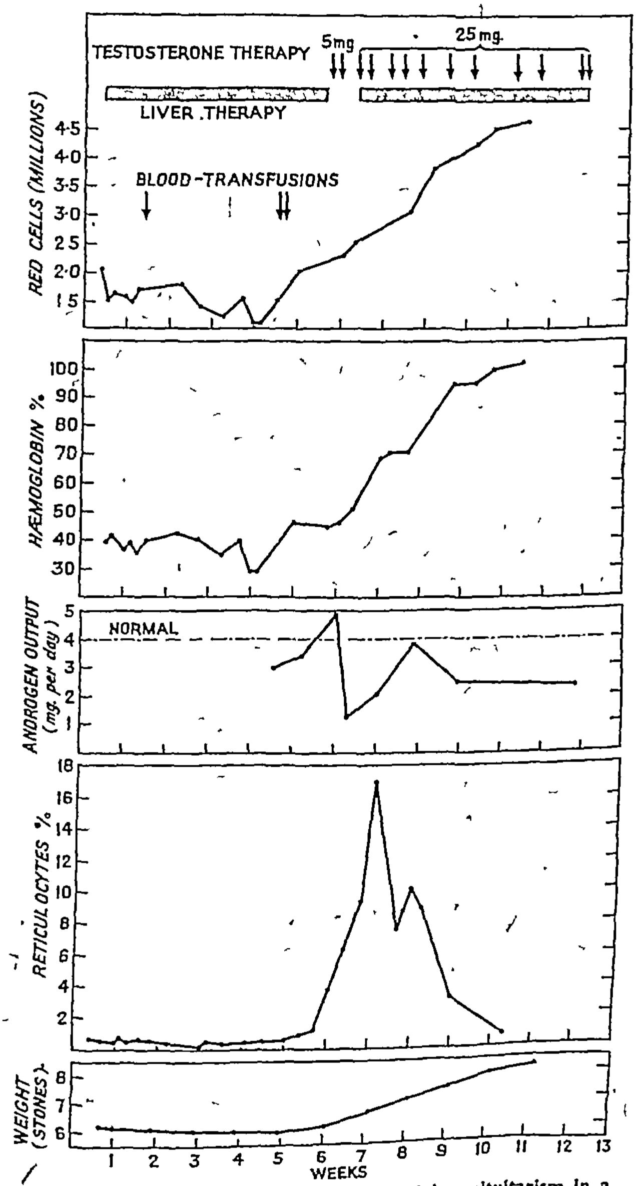

Fig. 1—Macrocytic anæmia, hypogonadism, and hypopituitarism in a man (case 1), showing lack of response to liver therapy alone but good response to testosterone and liver therapy.

injections and adequate doses of thyroid also failed to induce any improvement.

Testosterone propionate was then prescribed in addition to the iron, liver, and thyroid to combat the impotence. To our surprise the drug caused a striking improvement in the blood picture, producing a reticulocytosis of 8% on the second day, followed by a steady rise in the Hb concentration in the next month to 80% and a month later to 98%. For the next four months he remained well, the Hb level fluctuating between 90% and 98%.

It was thought desirable to decide which of the four drugs he was taking was causing the improvement in the blood. Accordingly all therapy was stopped and the patient allowed to relapse. In the next two and a half months his Hb level fell to 70%, and he was then readmitted to hospital.

Daily reticulocyte counts were made and the drugs given singly in turn. Iron was given for two weeks with no improvement; several liver preparations for a further three weeks; and thyroid for two weeks without producing any reticulocytosis. No success was met by giving testosterone alone in doses of 10 mg. daily for a week. Iron, liver, and testosterone were then given together, producing a reticulocytosis of 6% in the first week and a steady rise in the Hb level to 90% in the next two months.

When last seen the patient was well, Hb 98%. He was still taking 5 mg. of testosterone in linguets by mouth daily and was considerably stronger and more vigorous than previously.

The relevant features of this case are summarised in fig. 2.

DISCUSSION

These cases conform to the syndrome described by Snapper et al. (1937) and Witts (1942). Both patients were men, their ages 20 and 52, and their symptoms could be related to dysfunction of the anterior lobe of the pituitary, one showing infantilism, and the other feminisation. Pituitary deficiency was shown by the increased glucose tolerance. There was demonstrable improvement in pituitary function after treatment in the first case. Gonadal insufficiency was shown by small testicles and deficiency of secondary sexual characteristics in both patients, and lack of libido in the second. In the first case there was a reduction in excretion of urinary androgens, and the hypogonadism appeared to be of the secondary or pituitary type. Thyroid deficiency, as assessed by the basal metabolic rate, was present in the second case. Both patients had achlorhydria, the acid returning in case 1 after treatment.

The 8 published cases of this syndrome—hypopituitarism, hypogonadism, and anæmia—all responded to iron and liver. The present 2 cases, however, were resistant until testosterone was added to the treatment. It seems, therefore, that the hypogonadism was an important factor in the production of the anæmia, in the one case macrocytic and in the other microcytic.

Snapper et al. (1937) comment on the hypogonadism but think that the associated anæmia is pituitary in origin. They believe that the relation of the pituitary to the bone-marrow may be complex, and postulate that the polycythæmia and anæmia associated with hyperpituitarism and hypopituitarism may be apparent only, by reason of alteration in the water-balance mechanism of the body, which is controlled by neighbouring hypothalamic centres. They conclude that the anæmia is probably secondary to changes in gastric secretion, which are under pituitary control (Spence and Witts 1939).

Our cases suggest that gonadal deficiency is sometimes associated with impairment of erythropoiesis. Eunuchs commonly have an anæmia, usually of the hypochromic type. Burger and Witts (1934) noted that men with hypochromic anæmia were often of asthenic build and looked younger than their years.

The lower hæmoglobin level and erythrocyte count in women was at one time thought to be due to menstrual loss, but the work of Steinglass et al. (1941) on the effect of castration and the sex hormones on the blood of the rat seems to cast doubt on this theory. These workers have found that normal male rats have a higher red-cell count and Hb level than have female rats. Castration of male rats causes a fall in the red-cell count and a reduction in the percentage of reticulocytes, and examination of the marrow after a time shows it to be considerably less cellular than previously, with a reduction in the erythroid tissue. Testosterone brings about a brisk reticulocytosis, with a rapid rise in Hb and red-cell count to normal. Castration of a female rat causes an immediate increase in reticulocytes, followed by a steady rise in the Hb concentration and erythrocyte count to a level equal to that of the male rat. Examination of the marrow after a time shows it to contain more erythroid tissue than previously. If œstrogens are administered to such a castrated female rat, the regenerating marrow reverts to its previously hypoplastic state. They conclude that the male hormone has a stimulating action on blood formation, whereas the female hormone inhibits it. It is unlikely that the male hormone exerts its stimulating action through the pituitary, for the changes are greater in the hypophysectomised animal (Vollmer et al. 1939). Steinglass and his associates conclude that there is probably a direct action on the marrow produced by the general stimulating action of the male hormones on metabolism and somatic growth.

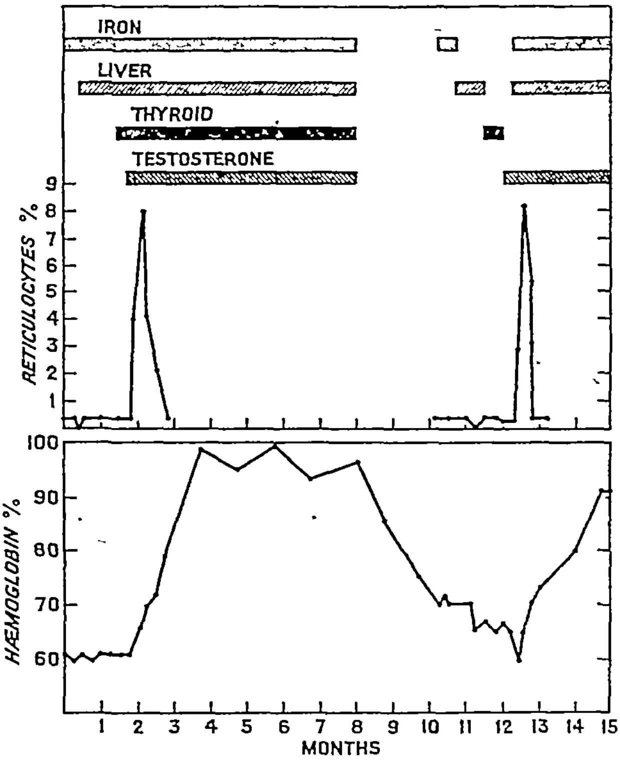

Fig. 2—Microcytic anæmia, hypogonadism, and hypopituitarism in a man (case 2), showing response to iron, liver, and testosterone therapy.

More recently, in a study of the action of the sex hormones on post-hæmorrhagic anæmia in rats, Finkelstein et al. (1944) have found that normal male rats, after bleeding, show a greater rate of regeneration than do normal-bled female rats. The administration of male sex hormone hastens, and a female sex hormone delays, the return of the count to normal. Blood regeneration is more rapid in the castrated female than in the bled castrated male. Male sex hormones accelerate erythropoiesis in both types. A similar effect is observed in the bled hypophysectomised animal. Combination with cobalt is more effective in castrated rats than either agent alone. Bone-marrow studies confirm the observations. These facts show the importance of the male hormone in erythropoiesis in the normal animal.

Our cases seem to conform well to the experimental findings. In both an anæmia had developed, probably *initiated* by pituitary deficiency and aggravated by long-continued hypogonadism. The deficiency of the sex hormone probably caused the reduction in cellularity of the marrow which was noted in both cases; it must be remarked, however, that assessment of cellularity by sternal puncture is unreliable.

The resistance of the anæmia to simple methods of therapy confirms this view. The administration of the male hormone corrected a long-standing deficiency and apparently enabled the marrow to utilise hæmatinic principles which it had previously been unable to do. The hormone alone in case 1 caused a small response in the marrow, which with the addition of liver became more pronounced. In case 2 the hormone alone failed to induce any improvement but with the other hæmatinic principles became effective.

In the belief that testosterone might benefit other refractory anæmias it was administered to 2 other patients, whose anæmia had proved resistant to treatment but in whom no evidence of pituitary or gonadal deficiency was present. The drug failed in these patients to have any persistent beneficial effect, confirming that it would only be effective in cases with gonadal deficiency. The drug induced a temporary remission in one case, suggesting that it is worth a trial in refractory anæmias, especially if associated with a hypocellular marrow.

Case 3.—A woman, aged 55, had an idiopathic aplastic anæmia resistant to all therapy. Medication with various liver preparations, iron, and thyroid failed to induce any improvement, and finally monthly transfusions became necessary. Testosterone 25 mg. twice weekly induced a temporary remission, with a reticulocytosis of 8% two days after the drug was administered. Three months elapsed before the next transfusion was necessary.

In view of the relapse of the patient splenectomy was done but had only a temporary effect. The patient died some fifteen months after the onset of the disease. Necropsy revealed extramedullary hæmopoiesis, and sections of the marrow showed the changes of primary focal myelofibrosis (Dr. Discombe).

Erf and Herbut (1944), in a survey of 13 cases of myelofibrosis of various types, used testosterone in 4 or 5 cases of primary myelofibrosis. They noted a temporary remission in 3 of them. They remark that this effect is hard to assess, because such cases may undergo temporary spontaneous remission, but they think the drug worthy of further trial in these cases.

Case 4.—A man, aged 68, had a severe macrocytic anæmia, with atypical megaloblastic transformation of the marrow. Free acid was present in the stomach, and the anæmia proved resistant to intensive parenteral and oral liver therapy. The anæmia seemed to conform to the descriptions given of achrestic anæmia (Israëls and Wilkinson 1940). Testosterone was administered here in full dosage for several weeks but failed to produce any improvement.

CONCLUSION

There seems to be little doubt that testosterone exerts a stimulating effect on the bone-marrow, and that it is indicated in the anæmia complicating long-standing hypogonadism or hypopituitarism which has proved resistant to treatment. It may be also worth a trial in other refractory anæmias, particularly those associated with hypocellular marrows.

Long-standing gonadal deficiency appears to reduce the cellularity of the marrow, which testosterone improves, either by restoring the cellularity to normal or by enabling the marrow to utilise hæmatinic principles which it had previously been unable to.

SUMMARY

Two cases of anæmia, one microcytic and one macrocytic, complicating pituitary and gonadal deficiency, conform to previous descriptions but are unusual in their lack of response to simple therapy with iron, liver, or thyroid, and in their dramatic response to testosterone propionate.

The relation of the gonads to erythropoiesis is reviewed, and a hypothesis is advanced of their mode of action.

Two further cases of refractory anæmia were also given testosterone; in one, a case of primary focal myelofibrosis, testosterone induced a temporary remission, as has been reported by other workers; in the second case, one of achrestic anæmia, it did not exert any beneficial effect.

The evidence produced shows that hypogonadism may be important in the production of anæmia, and testosterone may have a good effect in cases of this type.

Our thanks are due to Dr. H. C. Rook for allowing us facilities for studying case 1, and to Dr. George Discombe for his help in cases 2, 3, and 4.

THE USE OF CURARE IN ELECTRIC CONVULSION THERAPY

J. F. DONOVAN
M.R.C.S., D.P.M.

SENIOR ASSISTANT MEDICAL OFFICER, BRIGHTON COUNTY BOROUGH MENTAL HOSPITAL, HAYWARDS HEATH

PREMEDICATION with curare is a promising method of eliminating the risk of fracture in electric convulsion therapy (E.C.T.) (Bennett 1940, 1941, 1943).

During one year 29 patients having E.C.T. at the Brighton County Borough Mental Hospital were given premedication with curare, a total of 178 injections being administered. Two preparations of curare were used, *d*-tubocurarine chloride (Burroughs Wellcome) and 'Intocostrin' (Squibb). From the doses of the two drugs needed to obtain similar degrees of relaxation in the same patient *d*-tubocurarine chloride seems to be about five times as potent weight for weight as intocostrin. Prescott et al. (1946) state that 1 unit of intocostrin is equivalent in potency to 0·3 mg. of *d*-tubocurarine chloride, whereas the Council of Pharmacy and Chemistry (1945) reported that, by assay on rabbits, the provisional unit of intocostrin was equivalent to 0·15 mg. of *d*-tubocurarine chloride. The anæsthetics committee jointly appointed by the Medical Research Council and the Royal Society of Medicine are considering the standardisation of curare, and in the meantime think it inadvisable to rely on any dose-weight ratio.

DOSAGE

The manufacturers of intocostrin state that an average dose for E.C.T. is 0·5 mg. or units per lb. of body-weight, but the accompanying table shows that the dosage needed to obtain relaxation has only a rough relationship to body-weight. However, the dose needed to produce the same clinical effects at each treatment in the same patient is fairly constant, and no evidence of acquired tolerance was found.

A calculated dose sometimes produces too deep a paralysis or insufficient relaxation with the risk of fracture still present. It is therefore better to find the dose for each patient by observing the response to the curare. Thus, at the first treatment the curare is injected slowly and, as the signs of curarisation appear, even more slowly, and the injection is stopped before the desired degree of paralysis has been fully attained, allowance being made for further

DOSAGES OF CURARE WHICH GAVE ABOUT THE SAME DEPTH OF RELAXATION IN DIFFERENT PATIENTS IN RELATION TO THEIR BODY-WEIGHT

action of the curare for about 2 min. after the end of the injection.

The time taken for the first injection of curare has generally been about 4–5 min. At subsequent treatments the same dose can be given in 2 min. without altering greatly the depth of curarisation attained.

STAGES OF PARALYSIS

The patient's response can give accurate guidance in determining when sufficient curare has been injected only if the overall rate of the injection is kept fairly constant from patient to patient, and if one is well acquainted with the stages of development of curare paralysis. This follows a moderately clear-cut pattern.

At first there is mistiness of vision due to paralysis of the muscles of accommodation, associated with nystagmus and later with ptosis. The weakness of the ocular muscles spreads to the muscles of the face, and facial expression is lost. Speech becomes slow, hesitant, and dysarthric. At this point the main skeletal musculature becomes affected, the muscles of the spine and neck before the limb muscles. The head when raised from the pillow is moved jerkily, and contraction of the platysma is more evident than normal. At the next stage the head cannot be raised voluntarily and the patient cannot keep his arm held up from his side. The last muscles to be affected are the muscles of respiration.

A degree of relaxation just sufficient to make head-raising difficult or impossible seems to be all that is required for the effective control of the convulsions in E.C.T. Beyond the dose of curare necessary for this effect there still remains in most patients a reasonable margin of safety before the respiratory apparatus is paralysed.

APPARATUS

Before treatment is started all equipment necessary to deal with an emergency—e.g., mouth-gag, tongue-forceps, and airways—should be at hand. Sterile syringes already assembled should be available, including a 5 c.cm. syringe fitted with an intravenous needle for giving neostigmine. A resuscitation apparatus, consisting of an anæsthetic facepiece attached to a large rebreathing bag with an expiratory valve, which can be closed instantaneously, is used for the administration of CO_2 and O_2 during the first few inspirations after the convulsion. In the event of respiratory paralysis after the injection of curare the lungs can be inflated by closure of the valve and compression of the rebreathing bag.

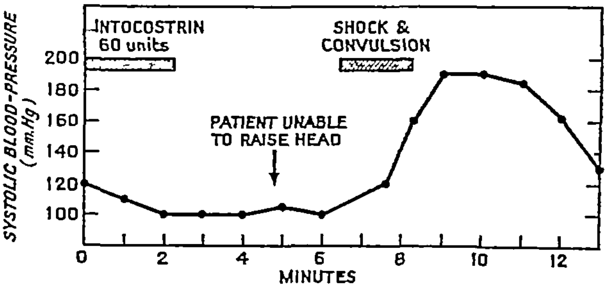
RESULTS

It is important that the effect of curare should have reached its peak before the electric shock is given. This peak is reached about 2–3 min. after the end of an injection if the time taken to give the injection is about 2 min. Recovery after the convulsion does not appear to be delayed in the curarised patient. Slight weakness and unsteadiness of gait may persist for a time after treatment but were so slight that 4 patients, who attended as outpatients, returned home accompanied by a relation in less than an hour after receiving treatment. The lassitude produced by the drug may not be altogether undesirable. One patient, who passed through a perfectly quiet recovery phase after convulsions controlled with curare, displayed such extreme restlessness after treatment without curare that he had to be given intravenous 'Pentothal.'

Complications.—No injuries occurred, and there were no serious complications. Curare does not normally embarrass respiration to any serious extent in the dosage required for E.C.T. Any tendency to alarm on the part of the patient because of mild respiratory difficulty was easily relieved by reassurance. As is well known, overdosage paralyses the respiratory muscles. If this happens artificial respiration should be given and 1–2 c.cm. of neostigmine (0·5–1·0 mg.) injected intravenously.

One patient, subject to bronchial asthma, developed bronchospasm after the injection of 15 mg. *d*-tubocurarine, and his respiration became strident and weak and almost ceased. Fortunately resuscitation overcame this condition. After a few more treatments on a reduced dose of curare with only mild symptoms the original dose was resumed without a repetition of the complication.

Another complication arose in a very asthenic patient to whom 60 units of intocostrin, calculated from body-weight, was given. At 5 min. from the start of the injection shock treatment was begun. The first two shocks were subconvulsive, but the third produced a major fit, at the end of which the patient's cyanosis faded into a grey pallor. He was pulseless, and his respiratory movements were feeble and ineffective. After the insertion of an airway and artificial respiration, pulse and breathing began again. On recovery he felt no ill effects apart from vomiting. Two days later, to determine his correct dose of curare, he was given 20 units of intocostrin. This produced almost complete abolition of head-raising for a short period. It seems possible that this patient may have belonged to a rare class who show undue sensitivity to small doses of curare (Cash and Hoekstra 1943).



Changes in systolic blood-pressure during and after injection of curare.

The only patient who showed signs of residual effects of curare was one in whom the first six treatments were with a combination of curare and pentothal. After the fifth treatment he developed a temporary and partial ptosis of the right eye. This reappeared and persisted longer after each subsequent treatment. At the end of the course of sixteen treatments the condition slowly improved, but remained to some extent for about two months. There was also some impairment of vision; but, because of his former mental state, it could not be determined if this had developed during treatment.

PHYSIOLOGICAL EFFECTS OF CURARE

Blood-pressure

During the treatments observations on blood-pressure changes were made on 5 patients by means of recordings at one-minute intervals. In 3 cases the systolic pressure was found on repeated occasions to be considerably raised and to fluctuate apparently with the degree of emotional tension experienced at the time. In another case the resting blood-pressure was 190/130, but during the injection of curare it ranged about 200/140 and rose to 220/140 with the onset of curarisation. One patient showed complete emotional indifference; his systolic pressure is recorded in the accompanying figure.

RESPIRATION

Recordings of respiratory movements of patients having treatment both with and without curare were made. Where curare was used these tracings showed no change in either the rhythm or range of respiratory excursion up to the point of development of paralysis of the neck muscles. Where deeper curarisation was attained respiration became shallower and faster. In 2 patients these changes were preceded by slowing of respiration. Even where there were some changes in the respiratory recordings there was no delay in the re-establishment of respiration after the convulsion.

SUMMARY

Premedication with curare is a promising method of eliminating the risk of fracture in electric convulsion therapy. This paper describes its use in the treatment of 29 patients receiving a total of 178 injections.

The disadvantages of calculating the dose of curare from the patient's weight are indicated. It was found better to inject the drug slowly, observing the stages of curarisation and allowing for the continued action for some two minutes after stopping the injection. The stage of curarisation to be aimed at is that in which the patient just cannot raise his head or can do so only with difficulty.

Curare has little effect on the recovery time after the convulsion. The few complications experienced are described and observations on blood-pressure and respiration are summarised.

I am indebted to Dr. W. McCartan, medical superintendent, for his help, Dr. R. Binning, of the honorary staff of the Royal Sussex County Hospital, for advice when treatment with curare was first undertaken, and Mr. J. Hughes, departmental nurse, for his technical assistance in recording observations and for his skilled direction of the nursing arrangements.

TREATMENT OF TROPICAL SPRUE WITH FOLIC ACID

R. J. G. Morrison
M.D. Lond., M.R.C.P.

C. R. St. Johnston
M.D. Birm., M.R.C.P.

LIEUT.-COLONELS R.A.M.C.

From the Queen Alexandra Military Hospital

The use of folic acid in the treatment of sprue has been described by Darby and Jones (1945), Darby et al. (1946), Spies (1946) and Spies et al. (1946a and b), but the only accounts of sprue treated in this country with folic acid are those of Manson-Bahr and Clarke (1946), Davidson et al. (1947), and Davidson and Girdwood (1947). Four cases of tropical sprue treated with synthetic folic acid are described here.

RECORDS

Case 1.—A soldier, aged 25, had served between April, 1943, and August, 1946, in India, Burma, and Malaya. In March, 1945, he complained of abdominal swelling, persistent diarrhœa, sore mouth, and loss of weight. In August, 1945, he improved after treatment with sulphaguanidine, but early in 1946 the symptoms returned and were again relieved with sulphaguanidine. He returned to England in August, 1946, and soon afterwards the diarrhœa recurred with general weakness and a sore mouth. In October he was admitted to a military hospital, where his fæcal fat was 70% by weight of the dried fæces, and a hyperchromic anæmia with achlorhydria was noted. Tropical sprue was diagnosed, and he was transferred to us for treatment, having had no specific therapy.

Investigation.—He was pale and sallow; weight 131 lb. Tongue red, shiny, and fissured; papillæ small. Abdomen distended and doughy. Red-cell count 2,470,000 per c.mm., Hb 60% (Sahli), colour index 1·2, mean corpuscular Hb 38%, hæmatocrit 32, reticulocytes 0 25%, white cells 5400 per c.mm. Sternal-marrow biopsy showed normoblasts 31%, megaloblasts 7·5%. The oral glucose-tolerance test produced a rather flat curve (fasting 125 mg., $^1/_2$ hour 150 mg. per 100 c.cm., 1 hour 131 mg., $1^1/_2$ hours 130 mg., 2 hours 126 mg., $2^1/_2$ hours 111 mg.).

Stools numbered 2–6 daily; they resembled soft putty and were offensive, the weight of 24-hour specimen being 28–60 oz. Radiography of gastro-intestinal tract showed that the stomach was distorted by the colon, which was much distended with gas. The descending and fourth parts of the duodenum and upper jejunum appeared somewhat distended, with loss of the normal feathery pattern.

Treatment.—After thirteen days on an ordinary ward diet there was no change in symptoms. On the third day of treatment with folic acid (20 mg. by mouth daily) he found he had more energy; the abdominal distension and discomfort were less, and the stools not so offensive. By the sixth day the number of stools had fallen to 1 or 2 daily, and the weight of the 24-hour specimen to 5–8 oz.; the stools have since this time remained between 1 and 3 daily, and of the same daily weight.

A daily reticulocyte count showed a rise to 2·5% on the third day of treatment, and reached a peak of 5% on the ninth. On the fifteenth day a blood-count gave Hb 76%, red cells 3,800,000 per c.mm.; sternal-marrow biopsy showed normoblasts 30%, megaloblasts 4·5%. The fæcal fat was 26% by weight of dried fæces, and he had gained $11^1/_4$ lb. He said his appetite had "changed from indifferent to keen" and that he could tolerate fats well. The dose of folic acid was reduced to 10 mg. daily.

On the thirty-fifth day of treatment he weighed 152 lb., and a blood-count gave Hb 92%, with red cells 3,910,000 per c.mm. The dose of folic acid was maintained at this level for a further four weeks and then discontinued. He now weighed 156 lb.; fæcal fat was 18% by weight of dried fæces; and blood-count gave Hb 78%, with red cells 4,400,000 per c.mm. Four weeks later, after being on leave and leading an active life without any treatment and on an ordinary diet, he felt well and weighed 154 lb.; his blood-count gave Hb 74%, with red cells 4,300,000 per c.mm., and mean corpuscular Hb 27%. Free acid had returned to his gastric juice, and there were no intestinal or other symptoms.

Case 2.—A colonel, aged 46, had served for over 20 years in India. In 1935 he contracted pulmonary tuberculosis, but made a good recovery. In October, 1944, he began to have dyspepsia, and lost more than a stone, but by July, 1945, he had regained his weight. In May, 1946, a month after an operation for transplantation of the right ulnar nerve, he complained of sore tongue and of ulcers in the mouth. He felt very weak, and had diarrhœa, loss of appetite, abdominal rumblings, and vague epigastric discomfort associated with a sensation of food sticking in his throat. He was sent into hospital on Oct. 18, 1946, with a diagnosis of pernicious anæmia.

Investigation.—He was thin and wasted, with a dry inelastic skin; the effort of walking about his room produced fatigue. Tongue smooth and fissured, with a small ulcer on the frænum. Abdomen distended and tympanitic; abdominal muscles poorly developed and atonic.

Stools numbered 4–6 daily, of the consistence of gruel, biscuit-coloured, bulky, and offensive: on standing in a glass jar yellow liquid pools of fat separated out.

A blood-count showed Hb 57%, red cells 3,300,000 per c.mm., reticulocytes 0·25%. The sternal marrow contained normoblasts 11·5%, megaloblasts 7·5%. A glucose-tolerance curve after 50 g. of glucose by mouth gave the following figures: fasting 88 mg. per 100 c.cm., $^1/_2$ hour 150 mg., 1 hour 130 mg., $1^1/_2$ hours 124 mg., 2 hours 118 mg., $2^1/_2$ hours 90 mg. No free hydrochloric acid was present after a fractional test-meal, and a fat analysis of stools gave 41% of the dried fæces. Radiography did not reveal any abnormal gastro-intestinal pattern.

Treatment.—On an ordinary ward diet, for three weeks, with rest in bed, the patient got steadily worse. On Nov. 7 treatment with folic acid 20 mg. daily by mouth was begun. Within 48 hours appetite had returned, dyspepsia had ceased, physical weakness had much diminished, diarrhœa had stopped, and stools had decreased to 2 daily, with the consistence of clay. The daily weight of the fæces fell from about 50 oz. to 10 oz., though subsequently it rose temporarily, probably owing to a dietetic indiscretion (a pound of grapes) due to a voracious appetite. At the end of the first week patient had gained over 13 lb.

A daily reticulocyte count showed a maximal rise of 7% on the seventh day of treatment. Sternal-marrow biopsy on twenty-fifth day showed normoblasts 21·5%, megaloblasts 1·5%. Fæcal fat had fallen to 35% after a month, and to 25% a week later. Fractional test-meal after treatment still showed achlorhydria.

The general condition and weight continued to improve, and on the thirty-seventh day of treatment his Hb was 95%, and the red cells 4,200,000. The dose of folic acid was then reduced to 10 mg., and finally on the sixtieth day to 5 mg. The patient is now living at home, and feels perfectly fit. In spite of walking eight miles a day his weight had increased to 152 lb. by the end of March, but his blood picture was still short of normal—red cells 4,100,000 per c.mm.

Case 3.—A major, now aged 59, had sore tongue, anæmia, and pale bulky frothy stools in 1936, and was treated for tropical sprue. A relapse in 1940 was treated with blood-transfusions and liver injections. He recovered, but lately had been feeling easily tired and had been passing bulky pale stools. In spite of liver injections his blood-counts had not been satisfactory. He was admitted to hospital on Sept. 4, 1946.

Investigation.—General condition fair; skin pale and parchment-like; tongue normal; abdomen distended; stools typical of sprue. Blood-count: Hb 73%, red cells 3,750,000 per c.mm., white cells 4950 per c.mm. An oral glucose-tolerance test did not reveal any flattening of the curve. Barium follow-through showed abdominal distension, with gas and pools of barium in small intestine. Fæcal fat 27% of dried stool. Fractional test-meal: achlorhydria. Sternal marrow: normoblasts 11%, megaloblasts 5·5%.

Treatment.—With no treatment beyond a full hospital diet, the reticulocyte count on Oct. 1 was 0·6%. Folic acid (20 mg. daily by mouth) was then given, but the reticulocyte count did not rise appreciably, and the blood picture did not improve. After sixteen days' treatment the hæmoglobin was 77% and red cells 3,140,000, and after fifty-three days' treatment the hæmoglobin was 64% and red cells 3,300,000. Folic acid was then stopped.

Though the bone-marrow did not respond, patient felt better. Stools were darker and less bulky and offensive, and fat-content had dropped from 27% before treatment to 12% afterwards. There was no gain in weight.

Case 4.—A nursing sister, aged 32, invalided home from India, was admitted in September, 1945. She had lost 36 lb. and complained of pale loose frequent stools, lassitude, sore lips and tongue, and abdominal distension.

Investigation.—General condition poor; weight 88 lb.; angular stomatitis. Blood-count: Hb 80%, red cells 3,000,000 per c.mm. Fæcal fat 26% by weight of dried fæces. No entamœbæ or parasites seen in stools.

Treatment.—Patient was given a high-protein diet, vitamins, and liver extract, and made slow progress. In February, 1946, she weighed 96 lb., had a red indented tongue, and was still passing loose stools with a fat content of 40% by weight: Hb 85% and red cells 4,100,000. In June, 1946, her weight was 97 lb., and as she was not improving all previous treatment was stopped and she was put on a low protein and high carbohydrate diet, with folic acid 15 mg. daily. The hæmatological response was negligible: reticulocytes reached a maximum of 2·5% on the eighth day; on the fifteenth day the hæmoglobin was 88% and red cells 3,700,000. There was, however, improvement subjectively and in the diarrhœa; stools decreased from 6 daily to 1–3 by the seventh day, and abdominal discomfort was less. A large dose of 100 mg. folic acid on the sixteenth day, followed by 20 mg. daily, with an ordinary diet, produced no reticulocyte peak and no change in hæmoglobin or total red-cell count. For another three weeks she had 30 mg. daily, after which folic acid was withdrawn.

On returning to the sprue diet, vitamins, and proteolysed liver by mouth, she continued reasonably well for four months. Folic acid (20 mg. daily) was again tried, with no effect on the reticulocyte or red-cell count, but with some improvement in her abdominal discomfort.

DISCUSSION

Cases 1 and 2, previously untreated, showed the expected dramatic response to folic acid; but in cases 3 and 4, which had both been treated for some time previously, there was no significant hæmatological response or gain in weight, though the gastro-intestinal symptoms diminished slightly.

Darby et al. (1946) described 3 cases of non-tropical sprue treated with folic acid, all of which showed a good hæmatological response; one of the patients had previously had liver therapy, and the response to folic acid was greater than with liver. In the case reported by Manson-Bahr and Clarke (1946) the patient had also had liver therapy for a long period and yet responded to folic acid.

The lack of hæmatological response in cases 3 and 4 is at present unexplained.

SUMMARY

The progress of four cases of tropical sprue treated with synthetic folic acid is described.

Two cases, previously untreated, showed a dramatic improvement both in the blood and in intestinal absorption.

The two other cases, which were of long standing and had long been treated with liver, were improved subjectively, but little or no effect on the blood was observed.

Our thanks are due to Lieut.-Colonel W. H. Hargreaves, O.B.E., R.A.M.C.; Messrs. Lederle Laboratories Inc. for supplies of 'Folvite' (synthetic folic acid); Major-General Sir Alexander Biggam, K.B.E., for his help and encouragement; Major W. R. Ashby, R.A.M.C., for the pathological work; and the Director General, Army Medical Services, for permission to publish.

Medical Societies

SOCIETY OF BRITISH NEUROLOGICAL SURGEONS

THIS society held its spring meeting in Lisbon on April 10 and 11 under the presidency of Sir Hugh Cairns. The meeting was arranged to pay tribute to Prof. Egas Moniz for his pioneer work. It was he who in 1927 introduced arteriography, which was used at first in cerebral work. The leucotomy operation for certain mental disorders was a later conception and was first performed by Professor Lima in 1935. The visitors, including members from several European countries, were welcomed by Professor Flores, of the Lisbon faculty of medicine, Professor Moniz's successor in the chair of neurology.

Professor Moniz spoke on thrombosis of the internal carotid and its branches, and on the interpretation of cerebral angiograms, especially the striking difference in circulation-rate through the internal and external carotid systems. Professor Lima described the diagnosis of subdural hæmatomas by arteriography. Professor Furtado and Dr. Marques spoke about the Arnold-Chiari malformation, Professor da Costa on the neuroblastomas, and Professor Fernandes on leucotomy. The technique of carotid arteriography was demonstrated by Dr. Imaginário and of aortic arteriography by Dr. dos Santos. An excellent exhibition of cerebral angiograms included the early experimental procedures and instruments used for them, now of interest historically. Several communications, mostly relating to Professor Moniz's work, were given by the visitors, including Mr. Norman Dott on intracranial aneurysms, and Prof. Geoffrey Jefferson, F.R.S., on frontal lobectomy.

Reviews of Books

The Rhesus Factor

G. FULTON ROBERTS, M.B. Camb. London: W. Heinemann Medical Books, 1947. Pp. 47. 3*s*. 6*d*.

THE rhesus factor was identified in 1940 by Landsteiner and Wiener, and not in 1939 by Levine and Stetson as suggested in this booklet. Most of the subsequent advances have been on the academic side and concern the geneticist; but the clinicians are responsible for blood-transfusion and obstetric practice, and they have been somewhat confused by rapid development of academic work and the many changes in terminology. Dr. Fulton Roberts has reviewed the subject, in 47 pages, for the average clinical reader; all the relevant information is briefly and clearly set out, and helpful case-reports illustrate the points raised. While the dangers of transfusing the Rh-negative person with Rh-positive blood are properly stressed, the potential dangers of transfusing the Rh-positive person with Rh-negative blood are somewhat overemphasised. Hæmolytic disease of the fœtus and newborn (erythroblastosis fœtalis) is often referred to as rhesus disease, which is an ugly term and not sufficiently comprehensive. But this good little book should help to clear up confusion for many.

Care of the Neurosurgical Patient

ERNEST SACHS, M.D., professor of clinical neurological surgery, Washington University, St. Louis. London: H. Kimpton, 1945. Pp. 268. 30*s*.

NEUROSURGERY more than other specialised branches of medicine depends on the integrated activity of a team. The efficiency of the team naturally depends on the acceptance and constant repetition of technical procedures, whose merits are sometimes less important than the standard of their performance by the team. This tendency has had two results: first, that the neurosurgeon passes on his rigid technique to others; secondly, that schools of method, rather than thought, have arisen—schools in which practical minutiæ have an important place. In this book Prof. Ernest Sachs has laid down the methods which he has perfected in his unit in St. Louis, with the principles and beliefs on which they are based. It is really a day-to-day account of his work, written in the first person and dedicated by name to the 28 neurosurgical fellows who have worked with him, and who will find in it a pleasing résumé of their training. Other neurosurgeons will find the technical descriptions too brief to be of great value to them, but general surgeons will get much guidance for their simpler adventures in brain surgery. The book cannot be regarded as a critical survey of the wealth of thought and activity which has in a few years produced modern neurosurgery. Such statements as "I have always felt that, irrespective of the ætiological factor, all headaches are due to positive or negative tension in the dura," and "Today, with the full use of ventriculography, over 97 per cent. of all tumours are located and removed," are scarcely acceptable. It would not be fair, however, to make too much of such shortcomings in the book, important as they are; for each chapter deals with action, and the development of technical perfection naturally limits theoretical consideration. Professor Sachs expresses his views clearly, and presents his techniques in short vivid descriptions, with plenty of case-abstracts and good illustrations.

Differential Diagnosis of Jaundice

LEON SCHIFF, M.D., associate professor of medicine, department of internal medicine, University of Cincinnati; director, gastric laboratory, Cincinnati General Hospital. Chicago: Year Book Publishers. London: H. K. Lewis, 1946. Pp. 313. 30*s*.

ANY monograph which makes for clear thinking on the subject of jaundice is welcome. By combining clinical, pathological, and biochemical data on the diseases causing jaundice, Professor Schiff hopes to expedite diagnosis and save patients from being "studied to death"; and he gives a complete review of published work on most aspects of jaundice. No short cut to diagnosis is offered, but each aspect of the causation of jaundice is fully presented. He attempts no synthesis of these into a plan of clinical and laboratory investigation suitable for any case. Close reading and close reasoning are necessary to follow him, but the reader is helped by plenty of first-hand case-histories and a good typographical layout. A summary of homologous serum hepatitis is included, though he recognises that advances in knowledge of the condition are proceeding rapidly. The chapters on clinical and laboratory aids to diagnosis are mercifully clear, and those on liver biopsy and X-ray examination well illustrated. He gives full instructions for the carrying out of laboratory tests, with references to the original papers; but a number of reagents mentioned are American proprietary preparations. This detailed book of reference is likely to be much used on both sides of the Atlantic.

Diseases of Children

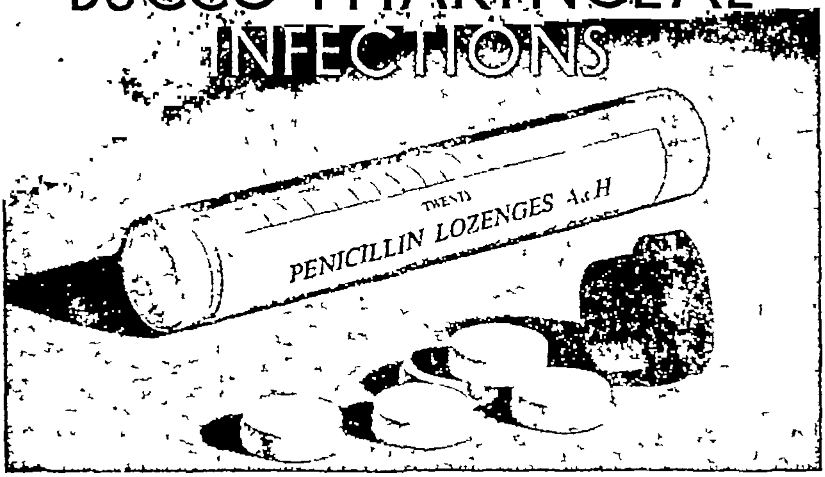
(4th ed.) Editors: DONALD PATERSON, M.D. Edin., F.R.C.P., physician, Hospital for Sick Children, Great Ormond Street; ALAN MONCRIEFF, M.D. Lond., F.R.C.P., Nuffield professor of child health, University of London. London: E. Arnold. Vol. i. 1947. Pp. 771. 30*s*.

THE 4th edition of this standard work, originally produced by Sir Archibald Garrod, F. E. Batten, and Hugh Thursfield, has been almost entirely rewritten and has changed its format from one large volume to two of more manageable size. The death of Dr. Thursfield in 1944 has removed the last of its originators; but the present editors have achieved, under considerable difficulties, a worthy successor to the previous three editions. By a pleasant innovation the list of contributors includes three American authors, who by reason of their Service duties had come into close association with their British colleagues. As before, the staff of the Hospital for Sick Children, Great Ormond Street, is widely represented in the list, and the editors have wisely included a number of relatively junior contributors. New material includes sections on growth and development, the use of sulphonamides and penicillin, clinical pathology, anæsthesia, and lung surgery, to mention only a few subjects in which great advances have been made since the last edition appeared. Each chapter is followed by a useful selection of references. The illustrations are perhaps a little unequally distributed, but for the most part are well chosen. If the second volume maintains the high standard of the first, this work will keep its popularity.

Textbook of Biochemistry (London and Philadelphia: W. B. Saunders, 1946. Pp. 592. 22*s*.).—The 4th edition of Prof. Benjamin Harrow's useful book covers more ground than is needed for most examinations in biochemistry in this country but can be recommended to students, though there are one or two errors in structural formulæ. The emphasis on the cyclic structure of the sugars is welcome, and it might have been carried even further. The field of biochemistry is well covered: there are chapters on immunochemistry and chemotherapy, and evidence from the use of isotopes is freely cited. The illustrations, too, are good.

***An Introduction to the Prescribing and Fitting of* Contact Lenses** (London: Hammond, 1946. Pp. 168. 42*s*.).—This book by two practising opticians, Mr. Frank Dickinson and Mr. K. G. Clifford Hall, covers the historical background of these lenses and their optical properties, and then relates how they are prescribed and fitted. A large trial set of lenses is used to find an approximate fit for the eye, and the lens selected is then ground until it makes a perfect fit. (The process of altering these lenses by grinding is not described, nor do the authors make clear whether this is done on the spot by themselves or sent away to a factory.) If the eye to be fitted is of such unusual shape that no stock lens is an approximate fit, a mould of the eye is taken with 'Zelex,' a dental impression compound, and a positive cast of this is made from dental stone. From this cast the contact lens is pressed. The process of taking a mould is clearly explained, but no account is given of the making of a lens from this mould. Not much is said of plastic lenses, which need elaborate machinery for their manufacture; but they seem likely, because of their lightness and smaller cost, to replace glass lenses entirely in time. Some first-class photographs make the process of fitting the lenses, and of detecting misfits, perfectly clear.

RATIONAL THERAPY IN BUCCO-PHARYNGEAL INFECTIONS



The Twenty-Lozenge Pack

Penicillin Lozenges A & H are issued in glass tubes to prevent inactivation of the penicillin by atmospheric moisture.

The number of lozenges contained in the tube (TWENTY) provides the most suitable package to meet the needs of individual treatment prescribed by the physician. Not only does it tend to eliminate waste but it assures the prescriber that the lozenges will not have time to become inactivated by exposure to a moist atmosphere before the prescribed treatment is completed.

Penicillin Lozenges A & H are indicated for the effective local treatment of bucco-pharyngeal infections.

In tubes of 20 Lozenges

PENICILLIN. LOZENGES A & H

PROLONGED CONTACT *antiseptic*

During a systematic investigation into the antibacterial activity of the monoaminoacridines, 5-aminoacridine emerged as an antiseptic having properties similar to those of proflavine. 'Flavogel' (5-aminoacridine) is the Glaxo preparation of this potent antiseptic in a water-miscible jelly base for use on cuts, wounds and protective dressings, etc. 'Flavogel' is valuable also as an antiseptic lubricant for catheters, cystoscopes, and specula, and in ante-natal examinations. 'Flavogel' has a powerful antibacterial activity, is effective in the presence of serum and is prolonged in action. The consistency of the jelly base maintains the antiseptic in contact with the tissues enabling it to exert the maximum antibacterial effect. 'Flavogel' is ready for application direct from the tube. It is convenient to carry, clean to use and does not stain skin or clothing.

'Acramine' (5-Aminoacridine) is available also as a powder for making up solutions.

FLAVOGEL

Manufacturers of Penicillin

5-Aminoacridine Hydrochloride in water soluble jelly base. 1-oz. tubes and 9-oz. jars.

Vitamin Therapy—its uses and limitations

AFTER ILLNESS

during which dietary restrictions or increased physiological requirements have reduced the body's stores of protective factors, recovery is facilitated if these are provided in adequate amounts. The composition of Complevite is so designed that each factor is represented in the proportions needed to bring the average daily intake up to the optimal physiological level.

COMPLEVITE

A *single* supplement for *multiple* deficiencies

The recommended adult daily dose provides :—

vitamin A	4,000 i.u.	vitamin C	20 mg.	iodine	not less than 10 p.p.m. each
vitamin D	300 i.u.	calcium	160 mg.	manganese	
vitamin B$_1$	0.6 mg.	iron	68 mg.	copper	

References Shortage of space precludes list of references, but full documentation may be obtained on application to Clinical Research Dept. 18B.

Infections and the Developing Embryo

SINCE 1941, when MCALISTER GREGG in Australia first drew attention to the connexion between rubella during pregnancy and congenital cataract, upwards of fifty papers confirming and extending his findings have been published in Australia, Europe, and the United States. There can now be no doubt that rubella during early pregnancy interferes with fœtal development and so produces congenital malformations, of which cataract, deaf-mutism, and heart disease are the most important. But there are indications that we have so far only touched the fringe of a larger problem. The knowledge gained in the last few years has opened up two lines of inquiry, one clinical and one experimental, which may substantially reduce the loss of life from prenatal causes and improve the quality of our infant population. Accurate clinical observations during pregnancy, with special attention to some details hitherto ignored, and the application of the experimental methods of the older amphibian embryologists to mammals should together lead to a new concept of the nature of sporadic congenital anomalies and so-called somatic mutations.

We know from the experiments of such pioneer embryologists as SPEMANN and ROSS HARRISON that a sublethal noxious influence acting on a developing embryo will, if it has any demonstrable effect at all, produce an anomaly of structure. This anomaly will be the direct result of interference with cells which are rapidly dividing at the time of application of the noxa; so its extent and nature will depend on the stage of development of the embryo at the time of the experiment. At a given stage of development the degree of protoplasmic activity varies in different parts of the body, and regions of high activity are electro-negative to those of low activity. These variations are directly related to susceptibility to poisons; curves of susceptibility can be drawn which will run parallel with the curves of electronegative potential and of metabolic and cellular activity for the same regions. The region of highest activity succumbs first to poisons in high concentration, but with low concentrations the most active region may be the quickest to become acclimatised. The experimental evidence has been almost entirely based on the behaviour of amphibian embryos, under the impact of such diverse agents as cyanides, alcohol, heat, cold, ultraviolet light, and alkaloids. Knowledge of mammalian reactions is scantier, but the action of X rays in permanently altering the layering of the developing retina in rats and in man suggests that similar experiments would give similar results. In all cases the resultant anomaly is specific for the stage of development at the time of the experiment rather than for the noxious agent used.

More work is needed on the placenta-passing properties of organic and inorganic, living and non-living, noxa; the data already obtained indicate a species variability. Many viruses as well as bacteria and their toxins are known to pass the placenta in man, and the earlier in development that a sublethal toxin acts the more likely it is to produce a congenital anomaly. When viruses, toxins, &c., attack the fœtus after the organogenetic period they reproduce more or less faithfully the disease seen in adults, modified by environment and the peculiarities of the fœtal circulation; they do not lead to developmental anomalies, except of structures not fully differentiated at the time. Good examples of the effects of virus infection after fœtal differentiation is well established are the cases of intrauterine smallpox, where placental transmission of the disease after the 4th month of fœtal life leaves the scars of modified pocks. When congenital defects follow maternal rubella, on the other hand, the mother's illness has usually occurred in the first 3 months of pregnancy. The periods of maximum cellular activity, and therefore of maximum susceptibility to attack, are for the developing lens the 4th to 8th week and for the internal ear the 7th to 10th week; and in the Australian series the average stage of pregnancy when the rubella occurred was for cataract 1·5 months and for deafness 2·1 months. So far, therefore, the evidence supports a time specificity, and it is strengthened by the case-report[1] of congenital buphthalmos where the mother had rubella in the 6th month of pregnancy, for that date coincides with early differentiation of the iridocorneal angle and of Schlemm's canal. Is there any evidence that infections other than rubella can produce similar results? So far the reports are scanty. SWAN et al.[2] in Australia have collected 18 cases of measles in pregnancy, 10 of them in the first four months, and 4 of the babies were born with defects; for mumps their figures were small but suggestive—6 cases, 5 with defects and 1 with a nævus; for varicella 2 cases, 1 with heart disease and 1 with a nævus; for herpes zoster 2 cases, both with defects; for scarlet fever 2 cases, 1 with obliteration of bile-ducts. LAFORET and LYNCH[3] report an example of extensive congenital defects following maternal varicella. Congenital defects have also followed maternal influenza,[4] hepatitis, and poliomyelitis.[4] In some of these the association was no doubt accidental, but the suggestive feature is the frequency of maternal infection at a stage of pregnancy which matches the defects in the child

Further inquiries, then, should not be confined to rubella, nor to one period of pregnancy, nor to one type of anomaly, but should be planned on a broad basis.

On the clinical side, antenatal supervision must begin earlier than has been the custom. As soon as pregnancy is diagnosed, all febrile illnesses, upsets, accidents, or shocks occurring since just before the mother realised she was pregnant should be noted. This detailed history should be correlated later with a thorough examination of all the infants, and with a study of the family history, to avoid misinterpreting genetic defects fortuitously associated with maternal illness. Teams of investigators working through the antenatal clinics might well tackle such inquiries; and at least one such team is already at work in this country. Next, all infectious diseases arising in pregnancy might be made notifiable; it would not be sufficient merely to ask for particulars of pregnancy on the present notification forms, because the "trivial" fevers, which are not notifiable, are important in this inquiry. The need is for all cases of infectious disease in pregnancy to be followed up, whether through the medical officers of health or infant-welfare clinics or otherwise. Experimental work on placenta-passing viruses in mammals may tell us when and how developmental anomalies originate. Rubella, it seems, cannot be transmitted to animals (with the possible exception of chimpanzees) but there are other viruses which attack some of the ordinary laboratory stock Lymphocytic choriomeningitis of mice will infect the embryo in utero, and canine distemper of dogs is worth considering as an experimental instrument It might be helpful to extend the experiments with X rays and chemical poisons to pregnant mammals, and to investigate their effect on the whole embryo at term and at different stages after exposure.

Meanwhile steps should be taken to protect women in early pregnancy against infection The proved danger from rubella and the possible danger from other infections should be widely known, so that pregnant women will do what they can to avoid contact with exanthemata to which they are susceptible An instance of intelligent propaganda is the recent notice sent to parents of boys at a big public school during a rubella epidemic, explaining the risks to sisters or other relatives who are pregnant Protection by means of convalescent serum is already under trial,[6] and if this is successful gamma-globulin prepared from such serum will no doubt become obtainable. But in prophylaxis, as in future research, the accent on rubella should not be so heavy that other infections, and perhaps trauma and malnutrition too, are excluded from consideration.

Hospital Admissions

THE cry is often heard that the general practitioner spends too much time on the telephone trying to get patients admitted to hospital. When doctors are being worked off their feet, this weakness of voluntary-hospital organisation merits attention.

Most hospitals do not know how long it takes a doctor to find out whether they will admit his case. However infuriated he may be, he seldom reports the matter, and he does not keep any note of the delays. The Emergency Bed Service, however, has kept a record of the times taken to admit patients to a group of large London voluntary hospitals in January. Some hundreds of calls were timed from the telephonist lifting her receiver to the receipt of a definite reply. The results are revealing. For a hospital with an efficient admission office, which keeps an up-to-date bed state and has the power to admit all types of cases, the average time taken was 4·8 minutes. (This includes dialling the number and being given the right extension by the switchboard.) Allowing for the fact that the extension is sometimes engaged, this average could hardly be reduced Another hospital which has no admitting officer but relies on the various housemen to admit emergencies took an average of 15 minutes to give a decision In the group as a whole it was clear that only those hospitals with a permanently-staffed admission office were consistently quick in replying.

The methods of admission differ considerably from hospital to hospital. Some are of an antiquated type dating from the days before the telephone, when the doctor sent a polite note to the honorary asking for his patient to be taken in. There are still hospitals which work on an admitting-ward system by which the wards take turns to admit urgent cases for a week, and in consequence patients may be turned away though there are some vacant beds in other wards. With the present shortage of beds this system may inflict gross hardship. The modern methods vary according to the size and layout of the hospital. Broadly speaking, they hinge either on an admission office, where someone with power to admit—not necessarily a doctor—is always on call, or on a resident medical officer who can be found rapidly by some kind of signals throughout the hospital The former is the more certain, and has the advantage that all admissions, whether from waiting-lists, the outpatient department, or other sources, and all discharges, go through the one office, which thereby knows the exact state of occupancy of the hospital and can answer the practitioner from information immediately at hand. An admission office, however, is probably warranted only in large hospitals. The alternative system, by which all admissions are made by a constantly moving R M O, will succeed only if satisfactory machinery is devised for finding the R.M.O. without delay and putting him in direct touch with the doctor. This is easy in a small hospital and difficult in a big one: but it is always simpler than attempting to link up the outside doctor with the right houseman, when there are perhaps a dozen to choose from

How far it is desirable for the admitting officer to be a medical man is a debatable point. At least one major hospital in London uses laymen for this purpose and maintains that it is wasteful to employ a doctor to answer questions that can with few exceptions be answered equally well by an office with an experienced staff. This view is supported by the fact that the doctors who admit patients are often the less experienced members of the profession, and do it for only a short time. Practitioners have been known to say hard words about young housemen who question their diagnoses without seeing the patient, and there is a lot to be said for permanent lay officers who cannot argue about a diagnosis but have learnt the right questions to ask. It seems hardly justifiable to keep a doctor permanently on duty merely to weed out the occasional case where the practitioner has drawn on his imagination for convenience' sake.

In the 750–1000-bed units of the future the admission system will be no less important. Since all types of case will be dealt with, the problems will resemble those of the present municipal hospitals rather than of the voluntary ones. But the practitioners' time will be no less valuable, and the admission office will make or mar their relations with the hospital service.

Dust in the Lungs

THE conference arranged in London by the Institutions of Mining Engineers and of Mining and Metallurgy provided an excellent opportunity for international discussions on the nature and prevention of pneumoconiosis in its various forms. The experience gained in the goldmines of South Africa was a fitting introduction, because they have had to face much the same man-power difficulties as those confronting the British coalmines today. Forty-five years ago fear of silicosis had made goldmining unattractive and there were few new recruits. By demonstrating that dust suppression could be effective and by assiduous training of new entrants the industry again won favour. Similar aims are in the forefront of the programme to attract young men to coalmining.

Prof. SUTHERLAND STRACHAN recalled that in the earliest days of goldmining on the Rand there were no regulations governing the work and it was not uncommon for a miner to die within two or three years as a result of exposure to dust. Today the first signs of silicosis rarely appear in less than 18–20 years, and even then the disease seldom produces functional disability, unless complicated by tuberculosis. The annual incidence of silicosis on the Rand is now less than a tenth of what it was in 1916, when systematic measures of prevention, detection, and compensation were introduced. The reduction in incidence has been attained principally by dust suppression but also by initial medical examination, whereby unsuitable recruits are debarred from working in the mines, and by periodical examinations for the detection and exclusion of cases of tuberculosis. Dust suppression has been a story of ingenuity and perseverance by mining engineers and ventilation experts. The measures employed in South Africa are water suppression of dust made in drilling and other operations, improved ventilation, arrangements of the times of blasting, and filtration of dusty air. Success has not been complete, because increased mechanisation has intensified the difficulties. The more powerful impact of modern machinery on rock has produced more and smaller particles, especially from the harder rocks. It is impossible to prevent the formation of these small particles, so the aim must be to deal with them at their source. Water will do much but not all, for some of the finer particles escape into the atmosphere even with the most efficient water-suppression methods; so adequate ventilation is needed in addition. A new form of drill, now in the experimental stage, extracts all the dust it forms, none reaching the miner's atmosphere. This is of especial importance in deep mining, where, on account of the heat, the use of water would so increase the humidity as to make working conditions impossible. Such conditions exist in the Kolar goldmines in India and may arise in the deeper mines projected in South Africa.

The results of dust suppression and medical supervision in the hæmatite mines in north-west England illustrate the great improvement that can be obtained. Dr. JOHN CRAW claimed that because of the control of dust, the selection of employees, and periodical medical examinations silicosis will probably cease to be a danger in these mines, though tuberculosis has still to be controlled. The main dust-suppression measure is the use of water-oil mist which rapidly brings down the dust generated during shot firing. In British coalmines the use of water and improved ventilation to control dust has been most actively studied in South Wales, where the incidence of pneumoconiosis is highest. Mr. J. IVON GRAHAM and Prof. T. D. JONES explained that the aim is to suppress dust whatever its source, whether it be from the coal seams or the rock strata. Where the coal is cut by machinery, water is brought to the site of cutting, and the dust at loading points is laid by water sprays. Wetting agents and foam are also used Another method, not applicable to metalliferous mines, is to infuse water into the coal seam before cutting, by boring holes and injecting it under pressure. The water seeps through the clefts so that when the coal is subsequently cut little or no dust forms. The amount of water introduced must obviously be regulated, for a wet working place can be uncomfortable and unhealthy. Most workers approve of this infusion method. A measure which has been reintroduced is the consolidation of dust along the roadways into a hard surface by applying calcium chloride. Supplies of the chemical are limited, but many miles of roadway in South Wales mines have already been treated. The attempts to suppress all forms of dust in coalmines are justified, since the pneumoconiosis of coal-workers is not a pure silicosis but due to the action of mixed dust. Dr. J. GOUGH compared the changes in coal-workers' lungs with those of goldminers and others showing classical silicosis. The few coalminers engaged principally on rock-drilling show classical silicosis, but those engaged on the coal face and in other operations in the mines and trimmers loading coal into ships show a different condition. Like classical silicosis, the disease in coal-workers is focal but the collections of dust show much less fibrosis. These changes correspond with the X-ray appearance now described as reticulation. The collections of dust are often accompanied by a characteristic focal emphysema, which appears to be more severe than that developing around silicotic nodules. The coal-workers' disease may be a modified silicosis, for coal always contains silica. It is now recognised that dust of relatively low silica content, such as commercial coal, can cause disability and fatal lung disease. Tuberculosis plays an important part in coal-workers' pneumoconiosis. The massive forms of fibrosis seem to be due to the combined action of dust and infection, usually tuberculosis. But open tuberculosis only occurs in a small percentage of cases, so the infection can rarely be diagnosed clinically. The fibrous type of tuberculosis is now more common in goldminers than the destructive form in which tubercle bacilli were readily identified.

The reactions which take place on the surface of silica particles are of great importance, because alterations of the surface can neutralise the toxicity. These surface effects form the basis of the use of aluminium in the prevention and treatment of silicosis. Aluminium forms a coating on the silica which reduces its solubility, and this seems a likely explanation of its antidotal effect. After aluminium treatment in Canada and the United States a high proportion of the men treated claimed to be benefited, but there was little objective evidence of improvement.

Further research is necessary, and the method will be tried out in Britain.

Mining engineers and medical men have worked too independently on the problems of dust disease, but better integration of effort and more consultation with each other is likely to be one outcome of the conference. An interdepartmental committee is to consider what more can be done in this way.

Almroth Wright

DISCOVERY is a process, not an event; and if we are not concerned with "what porridge had John Keats" we must be interested in the steps by which man climbs out of ignorance into knowledge. ALMROTH WRIGHT graduated in medicine in 1883, two years after PASTEUR had made the crucial test of the attenuated anthrax vaccine, and a year before METCHNIKOV described phagocytosis. The stage was set for applying the facts of practical immunology to man, and WRIGHT'S real life-work began with antityphoid vaccine. HAFFKINE and PFEIFFER having paved the way, he followed with all the vigour of an inspired personality. From successful prophylactic inoculation he turned to the therapeutic use of bacterial vaccines; but here success proved doubtful, and bacteriologists found themselves ranged in a battle whose sound still echoes. Then came his work on the opsonic index, done with the late S. R. DOUGLAS and based on METCHNIKOV'S studies in phagocytosis. The test they devised is now almost a thing of the past. But the modern theory and practice of absolute rest in tuberculosis owes it more than is generally supposed.

The first world war inspired his last great research, on the immunology of wound infection. The old drastic rule-of-thumb antiseptic treatment was unconscionably long a-dying, and WRIGHT gave it its quietus with hypertonic salt solution. Granted the right conditions, he believed, the protective mechanism of the body could deal with infection without antiseptics; and if today, thirty years later, polemics about this have ceased, and the stage is held by the sulphonamides and penicillin, it remains true that his courageous thinking and acting in the years 1914–18 pointed the way to a new conception of the infected wound. Dovetailed into all these fundamental researches was the practical bench-work which has influenced technique all over the world. He showed laboratory workers what can be done with a rubber teat and a piece of drawn-out glass tubing.

Always an uncompromising individualist, WRIGHT seemed to take little notice of what other people found out. Nor did he make much attempt to fit his observations into the corpus of accumulated knowledge. Nevertheless he took immense pains over exposition, and in his belief that language could be made a better vehicle of thought he invented a number of new words, some of which will survive. He had a great dislike of statistics, and was in many other ways wilful and wayward. Some thought of him as a hero; others as a grim lion, liable at any moment to turn and rend; others again as just a wrong-headed rebel. But none can now deny him the salutary influence of the original mind which invades the holy places of accepted dogma and sets up sign-posts in deserts. Often these signs have led us otherwhere than he or we expected, but they have kept us on the march.

Annotations

VITAMIN NEEDS OF MALARIA PARASITES

IT has been generally believed that malaria is favoured by malnutrition and that when a population is suffering from famine it is correspondingly less able to resist an epidemic of malignant or benign tertian malaria. In the main this is probably correct, since many dietary deficiencies tend to impair the defence mechanisms involved. But evidence is also accumulating that under special circumstances the malaria parasite may suffer from lack of vitamins in the diet quite as much as its host does. Thus infections of *Plasmodium lophuræ* in chicks are diminished in intensity if the chicks are suffering from a riboflavine deficiency[1]; presumably the parasite does not get enough riboflavine for its own metabolism. And it has recently been reported that *P. knowlesi* requires ascorbic acid, and that if the rhesus monkey suffers from even slight deficiency, too mild to be recognised as scurvy, the usual well-known virulent infection is replaced by a low-grade parasitæmia which does not end fatally.[2]

The most recent development of this subject concerns *P. gallinaceum* and pantothenic acid. It has been known that pantothenate is necessary for the growth of many bacteria such as hæmolytic streptococci. The multiplication of these organisms can be checked either by an actual deficiency of pantothenate or by the presence of some compound sufficiently like pantothenate to be taken up by the pantothenate-receptors of the germ, and sufficiently indigestible to resist further changes; such compounds block the receptors just as sulphanilamide blocks the receptors for *p*-aminobenzoic acid. In the case of hæmolytic streptococci blockage of the receptors can be produced in vitro and in vivo by pantoyltaurine.[3] *P. gallinaceum* requires pantothenate just as much as streptococci do, and if chicks are subjected to severe deficiency of this vitamin (so that growth is seriously stunted) the malaria parasite cannot develop properly in their red blood corpuscles and only very mild infections result.[4] The forms of this parasite which grow in the tissues, such as those which develop from the sporozoites, are not handicapped in this way; probably because the concentration of pantothenate in the tissues is always much higher than that in the blood. The results of pantothenate deficiency can be produced more conveniently by the administration of "homologue blockers" than by keeping the chickens on a deficient diet. The most active compound of this type so far discovered is pantoyltauramido-4-chlorobenzene, or, $CH_2OH{\cdot}C(CH_3)_2{\cdot}CHOH{\cdot}CO{\cdot}NH{\cdot}CH_2CH_2{\cdot}SO_2N(C_2H_5){\cdot}C_6H_5Cl$. When given to chicks in the diet, this compound is 4–16 times as active as quinine in controlling malaria due to *P. gallinaceum*. Since its antimalarial action is produced by blocking pantothenate-receptors, it can be neutralised by adding more pantothenate to the diet, but it requires 8 molecules of pantothenate to neutralise one molecule of the drug. (This is in great contrast to the sulphonamides, where one molecule of *p*-aminobenzoic acid neutralises over a thousand molecules of sulphanilamide.) The pantothenate utilisation of the chicken host is not nearly so easily upset as that of the parasite, and toxic effects do not begin to appear until more than 60 times the therapeutic dose is given in the daily diet. The symptoms produced by overdosage consist essentially in loss of weight and eventual death of the chicks; but in addition there is a striking increase in the proportion of immature erythrocytes in the circulating blood, though the total erythrocyte count is not changed.

These results, obtained with *P. gallinaceum* and chicks, are not directly applicable to man, for the vitamin requirements of the different species of parasite and of host are different. But they are of considerable scientific importance in teaching us to understand the metabolism of the malaria parasite; and it is heartening to learn that in these lean times even malaria parasites can be seriously inconvenienced by lack of their vitamins.

ANÆSTHESIA FOR THORACOPLASTY

OPINION is still divided on the best anæsthetic for thoracoplasty. At a recent joint meeting of the Tuberculosis Association and the anæsthetics section of the Royal Society of Medicine the advocates of local anæsthesia pointed to the advantages of retention of the cough reflex, absence of explosion risk, and low toxicity of the anæsthetic (though whether this holds true when large amounts are used may be doubted). Its opponents, on the other hand, spoke of the mental trauma suffered by the patient unless sedatives are given in doses large enough to produce virtually general anæsthesia.

The technique of local anæsthesia takes time and no little skill; the intercostal nerves must be blocked as well as the brachial plexus, while some operators block the cervical plexus and the vagi; and all this amounts to a searching anatomical exercise. General anæsthesia is less spectacular, but the patient is quiet, and he has no memory of what is otherwise at best an uncomfortable experience. Paradoxical movements can be controlled, secretions can be removed by suction, and hæmorrhage in the chest wall can be minimised by infiltration with adrenaline. It is evident that equally good results are obtained by local and general anæsthesia, so long as the methods are well used.

ELECTROCARDIOGRAM IN RHEUMATIC FEVER

WITH their strong clinical bias, physicians in this country have never paid much attention to the electrocardiogram in the investigation of rheumatic fever. Our American colleagues, though they have taken much more interest in the subject, are still undecided as to the incidence, and the significance, of the changes they have observed.

Among 6000 patients with rheumatic fever, most of them aged between 17 and 25, who were observed in a U.S. naval hospital, Filberbaum and his colleagues[1] found 898 with electrocardiographic changes. Arrhythmias were present in 119, including 18 with nodal extrasystoles, 2 with nodal tachycardia, and 1 with nodal rhythm. This relatively high incidence of nodal disturbances is attributed to increased irritability of the A-V node as a result of the rheumatic infection—a suggestion which is possibly supported by the observation of retrograde auricular contractions in a further 6 patients. The P-wave was altered in 98 patients; inversion of P, present in lead I on 9 occasions, in lead II on 10 occasions, and in lead III on 20 occasions, is attributed to a shift in the site of the pacemaker. The P-R interval was prolonged in 325 patients; but as prolongation was often seen in patients without rheumatic activity, its significance is questioned. Abnormal displacement of the S-T segment was found in 74 patients, in most of whom the displacement was permanent; only rarely was it associated with clinical evidence of acute pericarditis, and in view of its not uncommon occurrence in normal adults its significance in rheumatic fever is considered doubtful, except where it is associated with other electrocardiographic abnormality. Excluding cases where only T_3 was involved, changes in the T-wave were noted in 125 patients. These changes could not be correlated with variation in rheumatic activity, but the interesting suggestion is made that in young adults, in whom arteriosclerotic heart disease can be excluded, such changes may indicate involvement of the coronary arteries.

Another report[2] comes from a U.S. Air Force hospital and is based upon an electrocardiographic study of 60 successive cases of acute rheumatic fever. The most significant change was found to be in the P-wave, which was flattened or inverted, usually in leads II and III, in 8 patients. These changes are considered diagnostically significant, since in most the flattening or inversion coincided with periods of rheumatic activity. No correlation could be found between these changes and alterations in the P-R interval; so, unlike Filberbaum and his colleagues, these authors do not hold them to be due to alterations in the pacemaker.

These two groups of cases are not directly comparable, since relatively few of the first series were seen during the early weeks of the illness. Their implication for the clinician is twofold: in the first place the electrocardiogram must never be interpreted apart from the clinical picture; and secondly there is still need for a full and detailed study of the electrocardiographic changes in rheumatic fever.

THE INDIAN VILLAGER

IN 1944 the All-India Institute of Hygiene and Public Health carried out a sample survey of its "district," which is served by the Singur Health Centre. Apart from the standard vital statistics and the results of some special investigations, we have hardly any information, even approximate, on the extent and associations of ill health in India; so this survey is of more than local importance. Its main findings have now been set out in a rather hurried preliminary report.[3]

Singur Health Centre is situated in the Ganges delta, 21 miles from Calcutta, and serves an area of 33 square miles, including 68 villages with a population of 63,000 in 12,000 families. The economy is agricultural; more than half the men till their own lands, and almost a quarter are agricultural labourers. Industry, transport, distribution, and the professions thus account for less than a quarter of the men, while nearly all the women are housewives. Three-quarters of the population spend less than £15 a year, and 40% of the families are in debt. About 42% of the males over fifteen and 4% of the women are literate; a third of the boys and 5% of the girls attend school. The vital statistics carefully collected during 1944 provide an interesting check to the official records:

	Survey findings	*Local registration data*
Birth-rate	42·6 ..	30·5
Death-rate	22·8 ..	19·5
Natural increase	19·8 ..	11·0
Infant-mortality rate ..	137 ..	—

Local hygiene is described in familiar terms: there is gross overcrowding; most of the houses are badly lit and ventilated; only 7% of them have washing facilities and latrines; fly breeding is universal. Yet, despite this depressing environment, the majority of dwellings were judged "clean" or "moderately clean."

The most valuable part of the report is its account of morbidity at the time of the survey: 11·6% of the people were suffering from some illness—acute in 1·1%, chronic in 2·1%, and undifferentiated or undiagnosed in 8·4%, malaria and dysentery being the commonest recognised complaints. These figures were laboriously analysed in order to elucidate associations between ill health and economic status, occupation, marital state, educational opportunity, and the like. Unfortunately

the smallness of the numbers, and insufficient standardisation for age and sex, detract from the significance of the results. But there is no gainsaying the main facts—this figure of 11·6%, and the other crucial finding that "wage-earners," whether cultivating their own land or otherwise employed, lost on an average 24·5 days in the year, or a full working month, because of sickness; which is well over twice the pre-war figure in this country. This appalling load of illness is a prime cause of the general poverty which in turn promotes illness—the vicious circle so characteristic of Indian life today.

The investigators also tried to analyse the "general family outlook" on the cause, prevention, and cure of disease; and the assessments remain instructive when every reservation is made for their difficulty and subjective nature. Already, it seems, about 40% of the families have a "rational" as opposed to a religious, fatalistic, or superstitious attitude. But the "rational" medical service provided does not suffice even for those families who are ready for it. During 1943 between £600 and £700 was spent on hospitals and dispensaries, which attended to only 3–4% of the estimated volume of ill health. By contrast the villagers themselves spent £12,000 on private practitioners, more than four out of every five of whom are described as unqualified quacks. The preventive health services are in similar case: less than one in twenty patients with notified infectious disease were visited. General experience agrees with this finding that public opinion in India is already in advance of the available health organisation; and here is still another reason for pressing vigorously ahead with the Government's plans for reform.

This pioneer survey was perhaps a little too ambitious in scope; but much of value has been learnt, and its successors will be awaited with interest. The Calcutta school is to be congratulated on setting an example which others should quickly follow.

CHRONIC TROPHŒDEMA

LOCALISED œdema due to abnormal reactions of the subcutaneous tissue seems to have become more common since the war. The cases originally described by Nonne,[1] Milroy,[2] and Meige[3] were familial; in 22 of the 24 cases in one family reported by Milroy the œdema was present at birth, whereas in Meige's cases it appeared between five and thirty years of age. Sporadic cases arise at any time between puberty and the age of thirty or over. Women are mainly affected. Usually a moderate swelling begins over one ankle and spreads very gradually until the lower part of one or both legs is involved in a hard pitting œdema. This is originally pale, but the skin may become red and inflamed and cause a burning sensation. Patients occasionally give a history of a preliminary swelling resembling angioneurotic œdema. Many of them have neurotic traits. Histologically there is a thickening of the skin and subcutaneous tissue which may develop into a definite hyperplasia in the course of years. There is no evidence of venous or lymphatic obstruction or of cardiac and renal or myxœdematous origin. Parkes Weber and Schlüter[4] saw two cases in sisters who had a moderate hypertension. Abnormal distributions of the œdema have been described. Sézary and Grenet[5] described a case in a boy of 14 months who had œdema of the forearms and left side of the face. Apart from the preliminary swelling, there may be attacks of low fever, with severe abdominal pain and even protracted vomiting, while the œdematous area becomes inflamed and irritating.[6] Some patients say that the œdema fluid oozes freely from slight scratch of the skin. The fluid is thin, colo and tastes extremely salty. It seems that when a certain concentration of the chlorides is reached the patient reacts with vomiting in order to get rid of the surplus.

These localised œdemas are at present grouped under the name chronic trophœdema, coined by Meige, which seems preferable to Milroy's disease, Meige's disease, and the like. Although the various factors mentioned influence the condition, its ætiology is by no means clear. Bauer's[7] view that it is a congenital localised tissue anomaly seems to be quite feasible. The mechanism is therefore related to, though not identical with, that of localised myxœdema. The treatment is entirely symptomatic and accordingly not very promising. Permanent bandaging is sometimes useful.

INVASIVENESS OF CANCER CELLS

EVERY student of pathology is familiar with the invasive character of cancer cells, infiltrating tissue spaces, permeating the lymphatics, and disseminating as lymphatic and vascular emboli. But what is the intimate mechanism of their invasiveness? Coman[8] has tried to interpret this characteristic faculty in terms of three physical and chemical differences from normal and benign tumour cells—decreased adhesiveness, amœboid movement, and the liberation of a spreading factor which acts on adjacent normal tissue.

By micromanipulation Coman has shown that attached pairs of squamous cancer cells are separated by a third or a quarter of the force required for normal squamous cells or those from simple skin papillomata. As a result of similar experiments repeated in media with diminished amounts of calcium salts, and from the known fact that cancerous tissue is abnormally low in calcium content, he correlates the reduced adhesiveness with this finding rather than with relative rates of growth and amounts of formed intercellular substance. Coman had previously[9] confirmed the earlier work of Lewis and Gey,[10] which showed that in tissue-cultures of human carcinoma and sarcoma individual cells become detached and show active amœboid movement; this provides the second difference and aligns malignant cells with macrophages, leucocytes, and lymphocytes. Given detachment and amœboid movement, infiltration of connective-tissue spaces would be facilitated if an enzyme were present to dissolve the cement substance of adjacent cells, and Coman has now extracted a spreading factor, a hyaluronidase, from several malignant tumours, though this is not identified as the specific product of the cancer cell. However, the invasiveness of transplantable sarcoma in mice was not increased either locally or distally by the injection of hyaluronidase; neither did the virus-induced benign papilloma of rabbits show a greater tendency to become malignant. Coman therefore admits that the source of the hyaluronidase may be bacterial infection of the tumour and that anti-enzymes may be formed. He is forced by the negative results of his experiments to conclude that this factor is not essential to invasiveness.

These are interesting preparatory studies in an all-important field in which the ability of a cancer growth to evoke lymphocytic accumulation and stroma formation, and to invade, may yet be correlated with some physicochemical property related to abnormal cell metabolism.

The next session of the General Medical Council will open on Tuesday, June 3, at 2 P.M., when Sir Herbert Eason, the president, will take the chair.

HOSPITAL WARD PLANNING

T. S. McIntosh
M.D. Edin., F.R.C.P.E.

H. R. Coales
A.R.I.B.A.

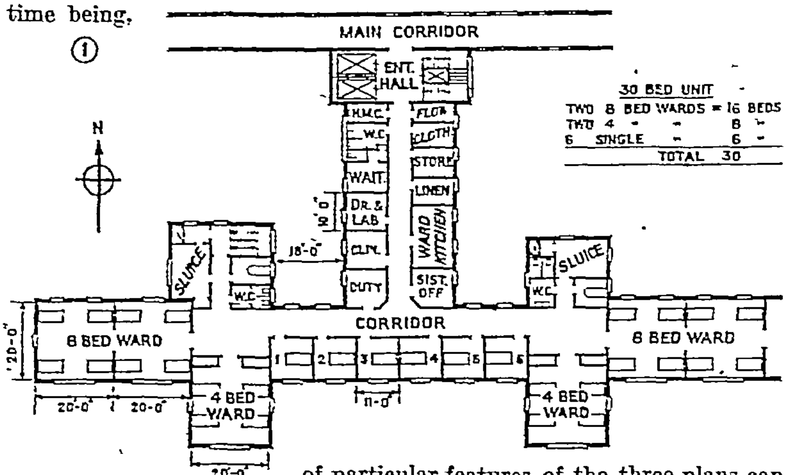
OF THE MEDICAL AND ARCHITECTURAL STAFF,
MINISTRY OF HEALTH

A hospital, besides being the doctors' and nurses' workshop, is the patient's dwelling for the time being, and ought, therefore, to be so designed as to provide hygienic conditions of a high order.

Good natural lighting and abundance of fresh air are well-recognised essentials of hygiene, which we should not be content to see neglected in hospital plans. Not only is the effect of good lighting on the patient's spirits important, but direct light has a beneficial effect on the body and reduces the bacterial count of the air[1]—a matter of obvious importance in a hospital, where infections of various kinds are always present and often abundant.

The trend of opinion in recent years towards smaller wards has complicated the architect's task. Whatever the drawbacks of the traditional British pavilion, its long rectangular wards with windows on both sides have at least the advantages of cross-ventilation and excellent natural lighting. Small wards of, say, 4 to 8 beds are less easily provided with cross-ventilation. On the Continent, where the small ward has been the vogue for a good many years, cross-ventilation has been almost entirely abandoned, and the usual plan consists in a series of small wards, mostly of 4 or 6 beds, ranged along a corridor giving access to them on the one side and to service rooms on the other. The wards thus have windows on one side only, and the internal corridor is mainly or wholly dependent on borrowed or artificial light. This is no doubt a convenient and economical plan, but it falls below the high standard of natural lighting and ventilation which has been a feature of British practice. The purpose of this note is to report an attempt to combine small-ward planning (including a liberal proportion of single-bed rooms) with good natural lighting and ventilation. It is a purely personal contribution to the study of hospital planning, made in the hope of promoting criticism and discussion.

①



Plans 1–3 illustrate three variants of the same general design. Each shows a ward-unit of 30 beds, composed of single-bed rooms and wards of from 4 to 8 beds. All the multiple-bed wards are cross-ventilated, and the single-bed rooms open off a very well lighted and ventilated corridor. The number of single-bed rooms is six in plan 1 and nine in the other two. Only plan 2 includes a dayroom, but this could equally well have been included in the other plans, and other combinations of particular features of the three plans can readily be made. The sluice-rooms and patients' sanitary accommodation and bathrooms are separate from the other ancillary rooms; one of the aims has been to combine convenience for the nursing staff with avoidance of disturbance to the patients by noise from ancillary rooms.

The allotment of ancillary rooms seems to us reasonably comprehensive, but no special virtue is claimed for their number or size. The plan can be varied by shortening or lengthening the wing which contains the main group of ancillary rooms and the lifts and staircase. In fact one merit that we claim for the plan is its adaptability: it can be modified in a number of ways to suit individual requirements and tastes, without departing from the fundamental idea on which it is based. The constitution of the ward-unit (small

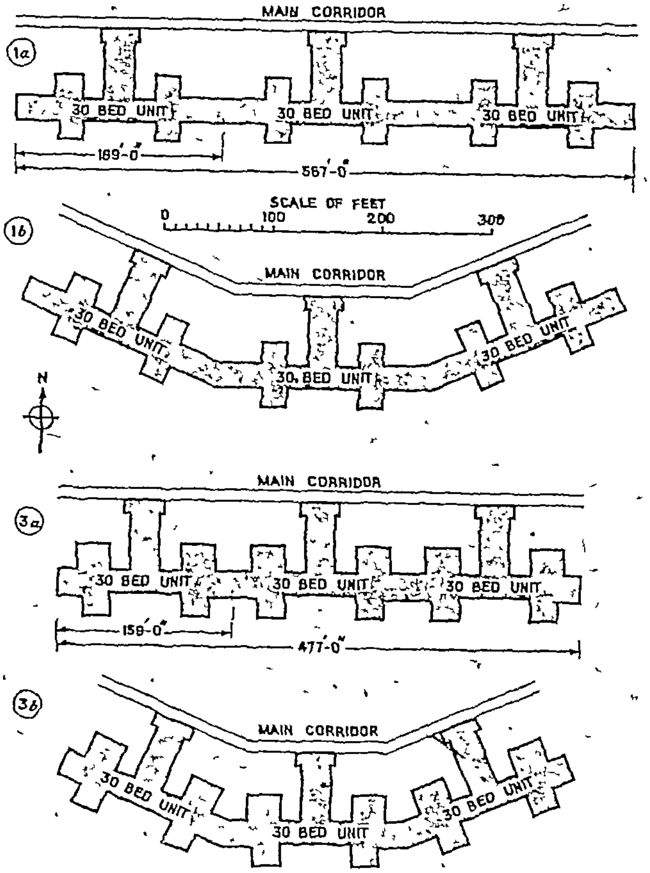
[1] Garrod, L. P. *Brit. med. J.* 1944, i, 245.

wards and numerous single-bed rooms) makes this form of planning eminently suitable for children. It is useful to be able to vary the use of parts of the hospital to meet varying demand.

A southerly aspect is assumed; due south would probably be best, but anything between south-east and south-west would be satisfactory. In plans 2 and 3, three of the nine single rooms have been sited on the north side of the ward-block, to avoid undue lengthening of the block. This may be no disadvantage since there would probably always be some patients for whom a southern aspect was not specially desirable.

Plans 1*a* and 1*b* (based on plan 1) and 3*a* and 3*b* (based on plan 3) show how the ward-blocks would be linked by a main corridor which would give access to the various central departments—offices, kitchen, laboratory, theatres, X-ray department, outpatient department, &c. Traffic in a hospital is mainly between the ward-units and the central departments, and little between one ward-unit and another. It would probably be unnecessary, therefore, to carry the main corridor above the ground floor; this would have the advantage that from the first floor upwards there would be no enclosed courts. The emergency doors which connect ward-units on the same level could be used by those members of the staff (e.g., doctors, matron, night superintendent) who have occasion to pass directly from one ward-unit to another.



A staircase is shown in one of the sanitary spurs of each detailed plan; this would provide an alternative means of escape in case of fire. It need only be provided at each end of a series of ward-blocks; the intervening ward-blocks would have an alternative escape at each end by the emergency doors leading directly into the wards of the adjoining blocks.

The plan is more suitable for a high than a low building, except in the case of small hospitals. Three ward-blocks of three stories would give 270 beds, and of six stories 540 beds. If a still larger hospital were required, three ward-blocks of eight stories or four ward-blocks of six stories would give 720 beds, and four ward-blocks of eight stories 960 beds.

Medicine and the Law

Damages against a Hospital for Alleged Negligence

THE facts established in the case of *Voller v. Portsmouth Corporation and others*, decided lately by Mr. Justice Birkett, will be studied with attention by hospital managements. A boy fractured his femur at football in 1944 and was taken off to St. Mary's Hospital at Portsmouth. Apparently it was not found possible so to manipulate the two pieces of bone as to bring them properly end to end, and it was decided to administer a spinal injection of 'Nupercaine.' This was done in the ward, not in the operating-theatre. A few days later meningitis was diagnosed. In the subsequent action for damages brought against the hospital it was stated that the patient is now permanently disabled; both legs are paralysed and he cannot retain his urine. According to the judge the defendants admitted that there could be no change for the better in the young man's condition and that this condition was entirely due to the spinal injection.

In spite of any such admissions, of course, the plaintiff would not succeed in his claim unless he could discharge the burden of proving that the defendants had been negligent and that their negligence had caused the loss and damage which he suffered. Besides the Portsmouth Corporation, sued as the hospital authority, three others had been cited as defendants—Dr. H. Hodges and Dr. S. F. Hans, both of the staff of the hospital, and Mr. A. G. Ord, visiting orthopædic surgeon. Mr. Justice Birkett found no evidence against these three and gave judgment in their favour. He found no evidence of any negligence in the treatment of the fracture, in the decision to administer a spinal injection, in the fact that the injection took place in the ward instead of in the theatre, or in the treatment of the patient after the meningitis was diagnosed. He was satisfied that the surface of the skin was properly cleaned before the operation and that Dr. Hans prepared himself in the approved manner by washing his hands and observing other requirements. How then had the unfortunate result occurred? After considering all possible sources of infection, the judge accepted the evidence of Mr. Hume Kendall (who was called on behalf of the plaintiff) that the bacillus must have entered the patient's body from outside at the moment of the injection and that there must have been some fault in the aseptic technique at the hospital. He thought that the hospital's technique in 1944 was adequate in this respect in the light of the knowledge then available. There must, he inferred, have been some fault in carrying it out. The evidence offered on this point by the hospital, he said, did not inspire him with confidence; it indicated a disturbing amount of confusion, forgetfulness, and carelessness on the part of the hospital staff for whom the Portsmouth Corporation were (under the ruling in *Gold v. Essex County Council* in 1942) legally responsible. The only possible source of infection was apparently in the apparatus used for the injection. There must have been a breach of the aseptic technique.

In giving judgment for £12,000 against the corporation, the judge observed that the plaintiff's loss had been calamitous. No money award could compensate him for his terrible disability. A stay of execution was granted with a view to an appeal. The court ordered the corporation to pay the costs of the three successful defendants, who were represented by Messrs. Hempsons on behalf of the Medical Defence Union.

The 1947 edition of the Register of Speech Therapists has now been published, and doctors, hospitals, and local authorities may obtain copies free of charge from the registrar of the Board of Registration of Medical Auxiliaries, B.M.A. House, Tavistock Square, London, W.C.1.

In England Now

A Running Commentary by Peripatetic Correspondents

PAINTING a doctor is rather like shooting a sitting bird. Their innocent confident faces beam across the galleries of this year's Royal Academy, announcing what they are from afar off. They range from James A. Grant's young surgeon, in pastel, grave and mild, through Dr. R. G. Abercrombie in John Wheatley's sinister yellows and purples, the universal Family Doctor of B. Fleetwood-Walker, and cosy Dr. William Crofton painted by John Y. Gilroy among some old books, to Vincent O'Sullivan, Esq., bagged by George Harcourt, and looking every inch the physician, surgeon, and gynæcologist his degrees in the catalogue proclaim him. These nearly exhaust the pictures of medical interest, for painters, tiring of wards and wounds and drips and rubber-tubing, have turned back to well-thumbed subjects—this under snow, that under sun, the market-place, the cornfield, the street, the bowl of flowers, and the occasional whopping nude.

Of course, it isn't what you paint, or even the jolly way you paint it, that makes a picture, I suppose; but something like a caged bird or a volcano which explodes out of the artist and gets on to the canvas. Perhaps eight years of war and peace are enough to stifle any volcano; and caged birds, fatigued by rationing, are too tame to leave the perch. But there was plenty of faint deliberate humour about, as well as some of the unconscious kind. Which was governing James Dawson when he painted two monstrous dogs and an attenuated man, and named it after the human? Derek Clarke's Connemara Family, with their glass-alley eyes, their red hair, their black hair, their long lips and thin legs, make their own jokes, even if they don't make a great painting; and the Sergeant-at-Mace of Gravesend, by Arnold H. Mason, provokes sympathetic smiles; the early cataract of his left eye proves on close inspection to be due to a trick of the lighting. With determined originality, Charles Ginner has painted the Albert Memorial.

When it comes to looking at pictures instead of subjects I am obliged to take further advice. The Nashes and the Pitchforths, I am told, are pleasant but not outstanding examples of these painters' watercolours; but I was distracted at the time by some Chinese geese. In missing the Churchills completely, though forewarned, I suppose I betray some deep-seated trouble with my œdipus situation. Conditioned, like my painted colleagues, by a professional bias, I found most pleasure in a picture called The Hospital Gate, by J. Leigh Pemberton. A stretcher-case was just going in, and since he had been brought in a cart and his legs were dangling over the sides of the stretcher, I am happy to report that this was not an English hospital. It was in fact a monkish Italian hospital of warm brick in a sun-ridden square, with a few inches of distant garden, shaded by cypresses, peering above its wall. Pigeons, a fountain, steps, and bronze lions no doubt place it for those who know Italy. I shall know it, when I see it, but more by the smell of the warm air and the sound of the fountain, I think, than by other marks of identification.

* * *

One of the snags in our department is the entertainment of Very Important People. Normally the laboratory is in an appalling state of untidiness but anything required is within easy reach. Petri dishes overflow with cigarette ends, meat pies sizzle in the incubator, and coffee cups lie strewn around. In this atmosphere the research worker, clad in stained flannels and filthy white coat or threadbare sports jacket, potters away happily hour after hour.

Suddenly all is changed. A V.I.P. is coming, he is *coming*, he is COMING! Far and wide is heard the cry, from the director to the lab. boy. The researcher shudders as a small army of grim-faced cleaners invades the laboratory. Gone are the pies, the Petri dishes, and the coffee cups. The laboratory is transformed into a cold impersonal spotless showpiece. Little work can be done for fear of exciting the wrath of the cleaners.

The great day arrives at last. The staff members are easily picked out as they huddle together in uncomfortable little groups, each worker resplendent in new suit and clean collar. The air is heavy with the odour of mothballs. The V.I.P. is duly impressed by the gleaming glasswork, and departs, convinced that much work is being done—and so it was, before his arrival. He has GONE, he has *gone*, he has gone! The cry is taken up joyously by all. The Petri dishes, the pies, and the coffee cups reappear and the researcher, clad in his oldest clothes, is again at peace with the world.

* * *

Whenever I read of allegations of inelegance or incompetence against the general practitioner in the domain of midwifery my mind goes back to one hot summer's day of 1928. I was acting as locum for Dr. S, who had a very large panel practice in an industrial town, and, during a hectic period of busy surgeries and visits, I was summoned to attend a well-to-do manufacturer's daughter in her first confinement.

My examination revealed an O.P. with a good deal of disproportion, and, after I had explained the position to the fussy and anxious parents, it was decided that I should call in a consultant obstetrician from the local university. The great man duly arrived, carrying his bare forceps under one arm and his gown over the other. His rubber gloves he produced from his pocket, and these, with the forceps, he handed to the midwife, with instructions to boil them. How she performed that task was not my business, for I was asked to get busy with the anæsthetic.

When the patient was fully anæsthetised and the obstetrician ready, I waited to see a masterly rotation performed, but no such thing was even attempted. He put on the forceps, and pulled and pulled, with his foot against the bed, until he succeeded in delivering the head, but not without causing a complete tear into the rectum; not even episiotomy did he perform. After the rest of the delivery, he turned to me and said that he thought he could safely leave me to undertake the repair. I, being young, could only meekly acquiesce and watch him depart, amid the plaudits of the relatives, with a fat cheque in his pocket.

This story should point a moral, but what it is I do not know.

* * *

In my train today there was a medical student, a tall untidy youth with a pale face. A medical textbook lay open on his knee, but his reading was half-hearted, and one gory illustration, in colour, remained displayed throughout the whole journey. As the train filled he was crowded into a corner, but the book stayed open though reading was then impossible. I watched with some amusement the efforts of at least three other passengers to see what was depicted—a sort of macabre fascination which they were at some pains to conceal. I was reminded of George.

George was in my year at medical school, a studious little man whose work, though intensive, always seemed misapplied. When we were preparing for the Second M.B. he was in the habit of carrying bits of his half skeleton about with him. One morning as he sat in the tram-car his right hand was absently playing with a scapula in his mackintosh pocket. The voice of the conductor roused him from his reverie, and, to his horror, he discovered that his thumb was stuck firmly between the acromion and the glenoid. He struggled for a little while and then grasped the bone with his other hand from the outside of the mackintosh while he pulled and pulled—all to no avail. The conductor looked at him curiously and said "Fares, *please*" in a louder voice. The other passengers began to take interest and poor George was in an agony of embarrassment. He couldn't face the idea of producing the bone, so he attempted the incredibly complicated manœuvre of taking money from his right-hand trouser pocket with his left hand. After a few wild moments which seemed like hours he succeeded and paid his fare, but the conductor went his way firmly convinced he had been dealing with a madman. I should dearly have liked to see George produce the scapula as a sort of gruesome appendage to his right hand. I can imagine the reaction of the passengers: the same sort of thrilled disgust as I saw today, the same mixture of curiosity and repugnance.

Letters to the Editor

THE CURRICULUM

Sir,—It is often said that, during the preclinical part of the medical curriculum, a complete interlocking of anatomy and physiology should be effected. But when the discussion turns to specific details rather than generalities it becomes clear that this ideal can only be partially attained, for in practice it is not always possible to equate the time spent teaching the anatomical and physiological aspects of an organic system. For instance the physiology of the circulation may occupy a whole term's course of lectures, while the study of the relevant features of the macroscopic and microscopic anatomy of the heart and main vessels may occupy not more than a few days. The study of the disposition and main attachments of the muscles of the body and of the structural mechanism of individual joints will occupy the student for many weeks; but, from the physiologist's point of view, the time devoted to the principles of muscle action and joint movement is very much shorter. Other difficulties arise from the fact that the more intimate study of anatomy by dissection of the human body proceeds in regions rather than in systems. The physiology of endocrine secretion, for example, may be dealt with in a single course of lectures, but the anatomy of the endocrine organs can hardly be studied in a single course of dissection.

This kind of limitation is obviously imposed by the practical methods of study which are employed in the medical curriculum, but it is difficult to see how it can be overcome. It means that, however much we should like to achieve the ideal of the simultaneous teaching of anatomy and physiology in respect of each functional system, in practice one or the other must come first (even if, in favourable cases, they are separated by little more than weeks or days). And, if this is so, which *should* come first?

For many years it seems to have been assumed, as I think erroneously, that the practical study of the anatomy of a system should logically precede the study of its physiology. But from the student's point of view this is altogether undesirable. The student who dissects the brain before he has studied its physiology tends to "learn it up" in bald terms of descriptive eminences and depressions, meaningless lumps of grey matter, and uncharted tracts of white matter. Or, if he studies the anatomy of the alimentary canal in the preserved cadaver before he has studied its movements during life, he inevitably gets a false impression of fixity and rigidity, however much the anatomist may try to persuade him otherwise.

Now suppose the student studies the physiology of these systems first. He does not need to have dissected a brain himself in order to understand and appreciate the principles of the elementary physiology of the central nervous system; the main topographical relationships which he requires to know in this connexion can quite easily be grasped by reference to dissected specimens, diagrams, and models. In the same way, he can perfectly well study the principles of the elementary physiology of the digestive system before completing a practical study of its anatomy. But if the anatomy of an organ is studied *after* some knowledge of its functions has been acquired the attitude of the student towards his dissection becomes quite different. To the intelligent student who has already studied the physiology of the nervous system the actual dissection of the brain becomes an interesting, and even an exciting, experience. For now he can display and trace out *for himself* structures such as the pyramidal tract, the medial fillet, the optic radiations, or the motor cortex, all of which will have acquired a real and vivid meaning for him. Similarly, in dissecting the stomach he will tend of his own initiative to look for those structures which now have for him a functional significance such as the disposition of the various muscular coats, the pyloric sphincter, the functional subdivisions of the stomach, and so forth.

It is in this connexion that a major criticism of Professor Zuckerman's plan for the Birmingham curriculum (*Lancet*, March 29, p. 395) may be suggested. Professor Zuckerman proposes to condense the whole of the dissection course into the first three terms of the preclinical period. But would it not be more reasonable to relegate it to the *latter* part of the period, by which time the student will have far more understanding of his subject and thus be able to derive much greater profit from his practical studies? Under the Birmingham scheme he will be compelled to dissect structures which, so early in his course, will mean little or nothing to him, and practical anatomy is likely to become for him an incredibly dull and dry subject. Another good reason for placing the dissection course towards the end of the preclinical curriculum is that, with surface anatomy and radiological anatomy (which should be studied concurrently with dissections), it leads naturally to the anatomical knowledge which he needs for the immediately following clinical part of his curriculum, and he will start his clinical work with this sort of knowledge still fairly fresh in his mind. In any case, it seems reasonable to deal with the general principles of anatomy in the early part of the preclinical period so as to give a general perspective of the subject, and to lead the student up to the more precise details of human anatomy later on.

Apart from other considerations, I am inclined to think it a psychological mistake to crowd the whole of topographical anatomy into an intensive course at the very beginning of the preclinical curriculum, as envisaged in the Birmingham scheme. The dissection of the upper and lower limbs and the thorax in the first term is specially open to criticism, since the average student, when embarking on a completely novel subject of the curriculum, does require a little time to settle down into it and to see it in its right perspective. It must also be recognised, I think, that there are definite temporal limits to the assimilative power of the human mind, particularly in its adolescent phase. While intensive courses can be tolerated quite well by the student in the later part of his curriculum, by which time his mind has become more mature, they are surely to be avoided in the early stages of a university type of education. It would appear preferable, on the whole, to space out the course of dissection over more than three terms; there seems no objection to this, provided the student's mind is not continually being distracted by having to learn and memorise masses of unnecessary details which have neither vocational nor educational value. The dissection course will then form a steady and somewhat leisurely, but quite fundamental, background to the more organised and integrated courses of instruction in which anatomy and physiology are brought into their proper relationship with each other. The student's knowledge of topography can be tested as he goes along, in this way eliminating as far as possible the necessity of memorising topographical details for the examination at the end of the preclinical period.

SONNE DYSENTERY AND NON-SPECIFIC GASTRO-ENTERITIS

Sir,—The subject of Martin and Wilson's paper of April 26 is one in which I have been interested since I was stationed in southern Scotland in the 1944–45 winter. At that time both Sonne dysentery and so-called non-specific diarrhœa were a problem for civilian and Service doctors alike. The cause of the non-specific diarrhœa being completely unknown, it was difficult to advise anxious laymen on methods of prevention—to say nothing of one's own anxieties about the possibility of a big epidemic.

At first the two diseases appeared different, and I wrote in a report: "The first is a febrile disease with a good deal of abdominal pain and frank blood and mucus in the stools, from which *B. dysenteriæ* Sonne is usually grown. The second is an afebrile diarrhœa, without much pain, and with a watery stool containing no gross amount of blood, on which the pathologist reports 'No pathogenic organisms seen.'"

Suddenly, in May, 1945, an explosive epidemic occurred in a camp, probably started by a Sonne-carrier in the cook-house, involving 23% of the men in the camp. Both types of disease were seen—the Sonne-positive dysentery and the bacteriologically negative non-specific diarrhœa, and all gradations in between. The Sonne-positive cases were mostly in the first three days of the epidemic, which lasted fourteen days. All the specimens were collected, dispatched, and tested under the guidance of experienced pathologists.

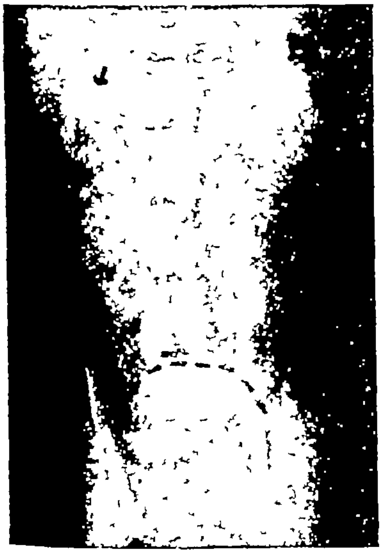
It is difficult to believe that two diseases with similar symptoms but different ætiology would break out at the same time in this way. Yet many think these are different diseases—particularly pathologists who have nowadays so much confidence in being able to isolate Sonne's bacillus.

London, E.C.2. I. D. MACDONALD.

PLACENTAL HORMONES AFTER DEATH OF FŒTUS

SIR,—Dr. Bernhard Zondek (Feb. 1) has shown that the placenta can continue to secrete hormones in a normal way for several weeks after the fœtus has died. On March 15 Mr. W. P. Hirsch reported a case of toxæmia with an eclamptic fit, all signs and symptoms having developed after death of the fœtus. Fœtal movements had been absent for four days, and on delivery a macerated fœtus was obtained and the placenta showed only small areas of old infarction.

Experimentally it has been shown [1] that the fœtus can be absent for months, even for the greater part of the normal length of gestation, without interrupting the state of pregnancy. For example, the fœtus was surgically removed from a rhesus monkey on the 73rd day of pregnancy while the placenta remained in place and functional, and the animal continued physiologically pregnant for the following 90 days, at the end of which time a viable infant would have been expected. Thus, in the monkey the duration of pregnancy and the onset of contractions associated with expulsion of the placenta were independent of the presence of the fœtus. Hormones in the urine were sustained at pregnancy level and did not drop until after spontaneous expulsion of the placenta.[2]



X-ray photograph showing distended ureter in a monkey on the 94th day of pregnancy. Interrupted line marks extent of uterus.

I wish to report an associated phenomenon. Hydro-ureter of pregnancy occurs in the monkey, as it does in women, during the latter part of pregnancy. The accompanying figure shows a distended ureter with urinary stasis in a monkey on the 94th day of pregnancy. The uterine shadow was not large enough to be compatible with a normal gestation of this length, nor was the fœtal skeleton to be seen. A hysterotomy was performed, and the uterine contents were removed as a whole. The placental size was comparable to that of a 60-day pregnancy; but, when the membranes were opened, no fœtus was found, though the point of attachment of the cord was clearly recognised. The amniotic fluid contained some debris.

In this instance, even after spontaneous absorption of the fœtus, the hydro-ureter persisted because of the presence of a functioning placenta. This conforms to our experimental findings, which show that a hydro-ureter can persist, or even arise, after removal of the fœtus early in pregnancy.[3] G. VAN WAGENEN.

SHORTAGE OF NURSES

SIR,—There is general apprehension that smooth functioning of the new health service, when it is introduced in 1948, may be hampered by shortage of nursing staff. Meantime the Ministry, the local authorities, and the voluntary hospitals are taking part in a campaign to recruit nurses to the hospitals.

It is generally agreed that one of the main reasons for the reluctance of girls to enter the profession is the persistence of old-fashioned restrictions, and the general tendency of the hospital authorities to interfere with the private life of the nurse. In order to overcome this obstacle to recruitment some local authorities have agreed that student as well as trained nurses may be non-resident. The General Nursing Council, in a circular dated April, 1946, state: "It is emphasised most strongly that the Council considers it to be to the disadvantage of a student nurse to be non-resident and every effort should therefore be made to arrange for her residence within the training school." In this the G.N.C. seem to take a stand which is directly opposed to modern tendencies, and wish to single out the student nurse from among most other students as being peculiarly unsuited to living away from her place of "study." Even in hospitals with the best of conditions there is no doubt that this policy turns away a number of potential applicants; but in many hospitals living conditions for nurses are highly unsatisfactory. In many mental hospitals noisy patients are liable to disturb even the soundest sleeper in the nurses' quarters, and the old custom of having nurses sleep in a side-room off the ward so that she may be available in an emergency has by no means been universally abandoned. Even in general hospitals a complete break with the institutional atmosphere once the period of duty is over is good for mental hygiene. The "student" nurse is primarily employed as a nurse and is only very secondarily a student; and since this position is unfortunately likely to continue for many years, its implications should be faced. In some hospitals compulsory residence (whether student nurses or trained staff) is as undesirable, and as unhealthy as compulsory residence at their place of work would be for factory workers.

St. Mary Cray, Kent. BRIAN H. KIRMAN.

BOOKS FOR MEDICAL "DISPLACED PERSONS"

SIR,—Excellent work is being done by our D.P. doctors in our hospitals, but they are greatly handicapped by shortage of textbooks describing the recent advances in the many branches and specialties of our profession. In Servatius Stift Hospital, Augsburg, of which I was medical director in the latter half of last year, there are 600 beds, five X-ray plants, and a chemical and a pathological laboratory, and all branches of medical and surgical work are encountered. Most of the doctors can read English and would welcome used textbooks or last editions but one. I am sure many of my colleagues have on their library shelves books which, though outdated by a couple of years, would nevertheless be very welcome to our doctors out here. All medical books are needed, but those on medicine and general surgery most urgently. I will gratefully acknowledge receipt of each book.

Area Team 1069, 390 UNRRA, B.A.O.R. P. J. SMITH.

AMPHETAMINE

SIR,—The article dealing with amphetamine in your issue of April 26 is doubtless based on a multitude of reports and must carry great weight the world over. Will you therefore once more allow a still small voice to register a minority report, and to record the following opinions and question?

1. The drug is useless in obesity because its power of diminishing appetite is lost after a very few doses.

2. It is most certainly not a specific cure for narcolepsy. It is perfectly true that a number of cases are very much relieved, but at a rough guess and as a clinical observer and not a research worker (that is all I can venture) it is effective in only half the cases.

3. Little or no mention is made of its possible toxic effects, and I feel strongly that the risk of these is still underrated. Since a previous communication which you published a few months ago (Jan. 4), I have seen yet

---

1. van Wagenen, G., Newton, W. H. *Surg. Gynec. Obstet.* 1943, 77, 539.
2. Dorfman, R. I., van Wagenen, G. *Ibid*, 1941, 73, 545.
3. van Wagenen, G., Jenkins, R. H. *J. Urol.* 1939, 42, 1010.

another case that developed a definite toxic dermatitis after very small dosage.

4. Because, in my opinion, its use impairs reason, it is of no value in the treatment of alcoholism; and I have not seen or heard any case-reports where a chronic alcoholic has derived more than temporary benefit.

5. It is agreed that the drug produces an evanescent euphoria; but in my experience the law of diminishing returns applies to amphetamine more surely perhaps than to any other drug in the pharmacopœia.

6. Its use may become a social danger, for it increases the average individual's capacity for swallowing alcohol without untoward symptoms; but the alcohol is then ingested in larger doses and the final pitiable picture is a mixture of alcoholic stupor and amphetamine excitement. This condition, apparent to an experienced eye, is dangerous to the victim, often producing disastrous consequences.

7. Is there a reputable psychiatrist who places the slightest reliance on the drug in the treatment of any psychotic or neurotic disease?

London, W.1. CHRISTOPHER HOWARD.

DEATH AFTER DOG-BITE

SIR,—Your annotation last week states that a boy died from anaphylaxis after the injection of 2 c.cm. of gas-gangrene antiserum. Some years ago Lamson[1] reviewed 42 such cases in most of which death took place within ten minutes of an injection of antidiphtheritic serum; and many others have been reported. Sensitisation to horse-serum is very common, and it is estimated that this fatality is likely to occur in 1–70,000 cases. But it can easily be avoided by a skin test.

If a control puncture is made, say on the front of the forearm, with an empty hypodermic needle, and another one is made two inches away through a drop of the fluid to be injected, redness, irritation, and a weal will be seen for certain within a quarter of an hour, at the site of the second puncture, in any patient who is grossly sensitive. If in such a case it is essential to give the injection this can be done by commencing with a dose of 0·1 c.cm. and continuing at half-hourly intervals, doubling the dose each time and giving three minims of adrenaline with each to anchor the dose and slow down its absorption.

London, W.1. FRANK COKE.

HÆMOLYTIC DISEASE OF THE NEWBORN

SIR,—I have read with great interest your editorial of April 5, discussing substitution transfusion in the treatment of erythroblastosis fœtalis and the possible effect of that treatment on prognosis.

You are quite correct in stating that the value of this method is limited in that it can be applied only after the infant is born. It is also true that complete reliance upon antibody studies as indications for treatment will occasionally lead us astray. We have recently observed an instance in which there was an antibody titre of 1 : 4000 in the mother's serum and 1 : 512 in the fœtal-cord serum, with anæmia but no jaundice in the infant. Recovery took place after a single intratibial transfusion given at two weeks. We have also seen an instance where no antibody, either complete or incomplete, was demonstrable in either the mother's serum or the fœtal-cord blood in a second pregnancy. We expected no serious illness and were greatly chagrined when after twenty-four hours the infant developed a severe and fulminating jaundice, dying within a few hours despite the substitution transfusion instituted at that time. Autopsy indicated that the procedure performed one day earlier might have been life-saving; but we were lulled into a false sense of security by the apparent absence of antibodies. Such experiences, fortunately, are the exception rather than the rule.

I agree that many of the infants will be so damaged in utero as to make the substitution technique useless. I do feel, however, that in the large group which appear normal at birth and yet develop severe icterus gravis within the next twenty-four hours the method is not only life-saving but also preventative of the unfortunate sequelæ of brain and liver damage. In the comparatively small series studied to date we find a mortality-rate of less than 10%, compared to our former figures of 50%.

---

[1] *J. Amer. med. Ass.* 1924, **82**, 1091.

There is no doubt in my mind that it is necessary to study a still larger series before the method can be properly evaluated.

In the long run, a procedure to prevent the formation of the maternal antibody will make all other methods of therapy obsolete. Until such a treatment is available the substitution transfusion appears to offer the best hope of a living and healthy baby to some families previously unable to anticipate that joy.

I wish to thank you for the favourable comment in your editorial, and to assure you and your readers that while we feel that some progress has been made in the treatment of the disease, there is still much to be done.

HARRY WALLERSTEIN

Erythroblastosis Fetalis Clinic, Jewish Memorial Hospital, New York. Director.

SURGICAL TREATMENT OF HYPERPIESIA

SIR,—In connection with your annotation of May 3, I suggest that the most dangerous complications are cerebral and retinal vascular accidents. They may depend upon the fact, often overlooked and not described, that the hyperpiesia is usually accompanied by spasm of the arterioles and capillaries, including those of the venous system. This spasm causes different degrees of hypertension in various parts of the vascular tree; a patient may have hypertension in the body, but hypotension in the brain. These cases are usually subject to myocardial failure or coronary thrombosis; and, if operated upon, they are liable to have cerebral hæmorrhage or thrombosis. The same applies to the retina.

A preliminary examination by Pachon's oscillometer and an estimation of retinal blood-pressure by Baillart's method would probably clarify the issue.

London, E.1. N. PINES.

ASCORBIC-ACID METABOLISM

SIR,—In their article (March 29) on the ascorbic-acid metabolism of Bantu soldiers, Professor Kekwick, Dr. Wright, and Dr. Raper express disagreement with several of the conclusions reached by us in a somewhat similar study published in 1940.[1]

It is unnecessary to discuss these divergences in detail, for some at least might be expected with groups whose circumstances and general levels of health are probably different. But we would like to stress that we have never supposed that the *ascorbic-acid requirements* of the Bantu differ from those of other races, or that the use of low daily intakes is to be condoned. Our main interest was to study the well-known fact that an extremely low daily intake of this vitamin may be found amongst persons doing hard work and apparently maintaining a high level of general health.

Obviously this type of experiment is open to many objections. The only reliable way by which extraneous factors can be excluded and the true *functions* and daily requirements of the vitamin established is by the study of healthy subjects consuming a diet believed to be adequate in all other respects. Such studies have now been made, and they have thrown much light on the subject; incidentally, they have fully confirmed the findings reported by us. The first of these was the classical experiment of Crandon[2] on himself, but several others may be mentioned—for example, the studies of Ancel Keys. Particularly relevant are two papers by Pijoan and Lozner[3] and Najjar, Holt, and Royston.[4]

The following conclusions may now be regarded as well established:

1. Ascorbic acid serves only two known purposes—the prevention of scurvy and the treatment of scurvy.

2. A healthy subject *initially saturated* with ascorbic acid, when placed on a diet devoid of this substance but otherwise adequate, will be protected against scurvy for as long as five or six months. The appearance of scorbutic symptoms —e.g., gum lesions and delayed healing of wounds—is sudden. (Until then the individual may be compared to someone approaching a precipice: though his danger is increasing

---

[1] Fox, F. W., Dangerfield, L. F., Gottlich, S. F., Jokl, E. *Brit. med. J.* 1940, ii, 143; with Suzman, H. *Proc. Transv. Mine med. Offrs Ass.* 1940, **19**, 240.

[2] Crandon, J. H., Lund, C. C., Dill, D. B. *New Engl. J. Med.* 1940, **223**, 353.

[3] Pijoan, M., Lozner, E. L. *Bull. Johns Hopk. Hosp.* 1944, **75**, 303.

[4] Najjar, V. A., Holt, L. E., Royston, H. M. *Ibid*, 315.

with every step he remains completely sound until the last step has been taken.)

3. At present the minimum daily intake required to protect from scurvy may be defined as that which maintains a constant level of ascorbic acid in the white-cell platelets; this appears to be of the order of 20 mg.—possibly somewhat less.

4. Safe dietary allowances lie somewhere between this protective minimum and about 80 mg. per diem, when saturation and wastage occurs. For normal subjects any daily intake within this range may be regarded as protective; but naturally the more generous the allowance, the greater the margin of safety.

5. Plasma values are useful as an index of ascorbic-acid status; but they merely reflect the degree of positive economy that is being achieved. (Roughly they indicate the distance to the precipice.)

It must be emphasised that the above is strictly true only for the average healthy person adequately fed in other respects. There is good evidence that individual idiosyncrasies cannot be ruled out entirely. Experiments such as our own and those now reported, carried out on groups of persons whose health is influenced by many other factors, will yield results which deviate from the foregoing according to the nature and extent of these other factors.

We submit that a consideration of the reports which have appeared in many parts of the world during the war years will support these conclusions as to the action of this vitamin. F. W. FOX.

South African Institute for Medical Research,
Johannesburg.

THANKS TO NURSES

SIR,—Mr. Hugh Donovan concluded his interesting article of April 19 by expressing his admiration for the nursing staff who cared for his patients. Acknowledgment of the part played by nurses appears all too infrequently in articles, and one can only hope that the omission is in no way due to their efforts being taken for granted.

London, N.6. P. ALWYN-SMITH.

ANALGESIA IN LABOUR

SIR,—I quite agree with Dr. Elam (April 26) about the lack of medical interest in maternal analgesia.

On Sept. 23, 1944, you kindly published a letter of mine advocating a mixture of alcohol and chloral, which I had found highly effective. Since then I have endeavoured to interest a number of general practitioners in the method, but without much success. On bringing up the subject I generally receive one of two answers—either that women appreciate their babies much more if they have some pain during childbirth, or that they do not really suffer all that much anyway.

Possibly this indifferent attitude may be due partly to the chronic fatigue from which many busy practitioners suffer and partly to familiarity with the sight of pain.

I shall be pleased to send a copy of my letter of 1944 to any who are interested. Using this method no apparatus is needed, and the actual administration of the mixture, which is given by mouth, may be safely left to the midwife. I have now given alcohol and chloral in more than forty deliveries; but I am still delighted when a patient, especially when she is a primipara, wakes up after it is all over and says, "when am I going to have my baby, doctor?"

46, Court Way, London, N.W.9. SHAKESPEAR COOKE.

"... If the psychiatrist is lost in a morass of theory, there is great danger that his ideas of scientific advances will drift into the sphere of wishful thinking and fairy tales. A psychiatrist must first of all be a good physician.... Second, he must be a bit of a sociologist who is a constant student of the milieu in which his patient has lived and must live in the future. Third, he must be a psychologist who understands the workings of the human mind. Fourth, he must be a vocational guidance expert. . . . Most important of all, the psychiatrist must express himself in terms which can be understood by every medical practitioner, and psychiatry must be made an integral part of medicine. It does not take a great mind to make simple things complicated, but it takes a very great mind to make complicated things simple."—Dr. C. C. BURLINGAME, *J. Amer. med. Ass.*, April 5, p. 971.

Parliament

ON THE FLOOR OF THE HOUSE

THE debate on the Transport Bill has provided one of the greatest—and most vociferous—clashes of opinion in the House during this session. Beginning on Monday with protests by leaders of the Opposition about the number of amendments and the shortness of the time allotted, it went on until Wednesday when a back-bench Conservative revolt, led at first by Sir Alan Herbert, from 9.30 P.M. until after 1 A.M. kept the division bells ringing and members marching through the Aye and No lobbies in an almost continuous parade. The packed hundreds streaming through the Government lobby joked and sang the Red Flag, the Internationale, Boys of the Bulldog Breed, and songs of the Welsh hills. A Conservative, rather lonelily, attempted Land of Hope and Glory, and someone asked A.P.H. why should he expect to have two funny shows running in London at the same time.

The announcement during the week of the terms of compensation for members of Indian services, including of course the I.M.S., has disposed of a cause of uncertainty and indecision. Reliable reports have it that in India the I.M.S. had hoped to have an announcement by the end of last year. The present announcement and its terms should satisfy them, and in view of the conditions a number of these officers may be willing to remain in India. One effect of the new relations with India upon which we are now entering is the greater understanding and friendliness of the Indian leaders. And there is everything to be said for coöperation of Indian and British continuing on a purely voluntary basis in the future.

Political gossip is busy with a possible unification of the medical branches of Navy, Army, and Air Force. This would certainly make some economies of personnel and would be of especial benefit in the case of specialists. But the Air Force does not like the idea, and the Navy points out that its medical personnel are necessarily trained differently from those in the Army. The shortage of medical officers, and particularly of specialists, has in point of fact brought about a very close coöperation of the three medical branches in such places as Malta and Ceylon. One line of argument against amalgamation is that the three Services have special medical needs: for example, the R.A.F. is particularly interested in hearing and middle-ear conditions and the Navy in vision. But the strong feeling aroused by the suggested change has a deeper source in Service traditions.

The Liberal opposition to the National Service Bill is to be carried forward in a number of amendments. The Bill provides for a period of compulsory full-time service for doctors and dentists on the same terms as other people—except that members of these two professions will be called up as officers. There is also a further provision of service in the reserve, making a total of 7 years. The total period of reserve service is to be not more than 60 days, of which not more than 21 shall be in any one year. The reserve service is therefore to be very much on the lines of Territorial service before the war. As it will be the link joining medical and dental officers with the Armed Forces and keeping them up to date, it could not be dispensed with without creating difficulties.

The main feature of the National Service Bill will be the change from 18 months' service to 12, which may lead to other modifications. But if we are to meet possible emergencies, trained men are a necessity, and if the proposals for a United Nations force made by the military staff committees of the United Nations are realised, medical and dental officers will be necessary for that force also. It is hoped that the international police force will gradually do away with the necessity for national services of the present-day pattern.

MEDICUS, M.P.

FROM THE PRESS GALLERY

Scottish Bill in the Lords

In the House of Lords on May 1 Lord MORRISON moved the second reading of the National Health Service (Scotland) Bill, which has already passed through the House of Commons. In briefly reviewing the provisions of the Bill he said that in the new family-doctor service, which closely resembled the Highlands and Islands system, doctors would be encouraged to work in groups and provided with premises, equipment, and ancillary staff for their work. In Scotland the duty of providing these health centres was imposed on the Secretary of State. The second division of the Bill covered the services administered by the local authorities. Lord Morrison admitted that the transfer of hospitals from those authorities would diminish their direct interest in the treatment of disease. In future their most important functions would lie in the social and preventive side of health work.

There were three important points in the hospital organisation proposed for Scotland which differed from the English Bill. The ambulance service would be made the responsibility of the Secretary of State instead of the local authorities, which had smaller areas than in England. Again in Scotland all hospitals, including the teaching hospitals, would come under the regional boards. The special position of the teaching hospitals would be recognised by the inclusion on their boards of management of members nominated by the university and the teaching staff. The reason for this difference was that though the number of beds in Scotland was only about a tenth of the total for the United Kingdom, Scotland was training a third of the medical students. If standards of teaching were to be maintained the bulk of the clinical facilities must not be confined to a few hospitals. Yet if even the main teaching hospitals were excluded from the scope of the regional boards the core of their services would be removed. The third difference was the establishment of a Hospital Endowment Commission for Scotland, which would be charged with the duty of reviewing the allocation of endowments having regard to the spirit of intention of the donor.

The Earl of ROSEBERY criticised the proposal to place the responsibility for the health-centre development in the hands of the Secretary of State. He did not see why the local authorities should have this power taken away from them. He was glad that the Government had agreed that in Scotland there should be no ex-officio officers of the Scottish Health Services Council. On the other hand, the teaching hospitals were to be taken under the ægis of the Secretary of State, and the Bill went out of its way to destroy not only the independence of those hospitals, but also their prestige. It seemed ridiculous that the teaching hospitals in Scotland should be administered in the same way as a small cottage hospital in the Highlands. He hoped that the Government would allow the hospital staffs to be directly under the hospital management. In England endowments were to be left to the teaching hospitals and grants were to be given directly by the Minister. But in Scotland these endowments might be reallocated anywhere else. The endowments of teaching hospitals in Scotland should be allowed to remain, and if the Government wanted more money for some smaller hospitals they should give a grant out of national funds.

He also pleaded for a grant-in-aid for better dentistry. As the Bill stood there was provision only for a uniform standard of dentistry, and dentists felt that this would result in utility dentistry throughout the scheme. If there was to be only one standard of work, that would benefit the least conscientious type of dentist. The principle of bringing professional men down to a low average standard ran right through this Bill, and that was one of the reasons why it needed so much amendment.

The Earl of SELKIRK agreed that a regional system of hospitalisation in Scotland was inevitable, and that they could not have a regional scheme, particularly for the south-east, without including the Edinburgh Royal Infirmary. But it was vitally important that the position of the teaching staffs should be safeguarded, and Lord Selkirk thought that the universities were profoundly anxious about the situation. They saw no chance of ensuring that they would be able to appoint the teaching personnel which were necessary. They did not even know if they could appoint their own professors of surgery.

Part v of the Bill, which dealt with the Board of Control, could not by any stretch of imagination be said to disclose a comprehensive service. Were the members of the board to continue to hold royal commissions, he asked, and what was their position to be in relation to the Department of Health? Would the reports of the commissioners be available not only for the general board, but also for the hospital boards and the regional boards?

Replying to the debate, Lord MORRISON denied that any powers were being taken away from local authorities. If it was objected that the Secretary of State was taking too much power, it must be remembered that less than 5% of the cost of the service would be met from local rates. Nearly 20% would come from national insurance contributions, and the rest directly from the Exchequer. In a service which was centrally financed to this extent it was essential that there should not be areas where the standard of the service provided was much below the general level.

Briefly, the general principle of part v of the Bill was to assimilate the mental-health services with the rest of the health service. Some of the supervisory functions hitherto exercised by the board were extinguished for the responsibility of providing and running mental hospitals and mental-deficiency institutions would in future rest with the Secretary of State. In performing these functions he was required to consult the General Board of Control. The board would continue to exercise all its existing functions relating to the liberty of the subject and the interests of the patient as an individual. It would also continue to exercise supervisory functions relating to private mental institutions not taken over into the new hospital service. In practice a system of dual appointments was envisaged whereby the medical commissioners —that was. the medical members of the General Board of Control—and also the medical officers employed by the board would, at the same time, hold appointments as officers of the Department of Health.

Indian Services and Compensation

IN the House of Lords and House of Commons on April 30 statements were made on the compensation for the premature termination of their service in India to members of the civil services and to regular officers and British warrant officers of the Indian naval and military forces and the Indian medical services.

In the Commons Mr. ATTLEE said that the Government of India were anxious to avoid the loss of experienced officers and they were prepared to give to those members of the Secretary of State's services who continued to serve them the same terms as to scales of pay, leave, pension rights, and safeguards in matters of discipline as hitherto. Provincial governments were being asked to give a similar assurance. H.M. Government accepted the obligation to see that European officers, and those Indian officers in the three special categories, should receive compensation for the loss of their careers and prospects consequent on the transfer of power.

Mr. Attlee's statement and the announcement made by the Viceroy in New Delhi have been published together with tables on compensation as a white-paper (Cmd. 7116. H.M. Stationery Office. 3*d*.). Table II which applies to regular medical officers of the I.M.S. includes the following figures:

Age last birthday (years)	Amount	Age last birthday (years)	Amount	Age last birthday (years)	Amount
	£		£		£
24	375	35	4500	46	3375
25	750	36	4875	47	3000
26	1125	37	5250	48	2625
27	1500	38	5625	49	2250
28	1875	39	6000	50	1875
29	2250	40	5625	51	1500
30	2625	41	5250	52	1125
31	3000	42	4875	53	750
32	3375	43	4500	54	375
33	3750	44	4125	55	—
34	4125	45	3750		

Note.—Officers who transfer to the British Services will receive one quarter of the rates laid down.

Plight of Old People

On May 1, in calling attention to the plight of our old people Lord AMULREE asked whether the Government intended to carry out any of the recommendations of the Nuffield report published in January. In 1900, he said, there were about 1 million people who might be called old. By 1947 that figure had increased to about 5 million, and, if the present trend continued, by 1980 here would be about 9 million. Today if old people ook advantage of the various systems of pensions they ould provide themselves with an adequate but austere ompetence. Their real problem was not poverty but he general difficulty of carrying on their normal way f life. The number of people who were getting into he ranks of what one might call the medically, not nancially, destitute was increasing, largely because hey could not take care of themselves. Many were uffering to a greater or less degree from under-feeding, ot because the rations were inadequate but because hey could not stand in queues and carry home large undles. When these old people were admitted to a ome and were given a normal adequate diet their ealth improved enormously.

Could not local authorities, he asked, supply meals o old people's clubs? He also suggested that homes or old people should be brought under some form of nspection. In a recent circular the Ministry of Health had urged local authorities to provide for old people easonable homes, with 30–35 residents, complete freedom, nd frequent visiting hours. In conclusion Lord Amulree urged that all old people who need hospital treatment hould be admitted for investigation to a general hospital, nd that their treatment, even if carried out in a separate uilding, should be under the supervision of the expert staff of an acute hospital.

Lord **Henderson**, replying for the Government, said much had already been done. The increased pensions had at last brought real security to most old people. Their health needs would be met by the National Health Service. He welcomed the suggestion that hospitals for the long-term sick should be more closely linked with the acute general hospital. Under the new service many of the chronic-sick hospitals might well cease to exist and long-term patients be admitted to special wards of general hospitals. Under the National Health Service spectacles, artificial teeth, and hearing-aids would also become available without charge to old people who could not afford them. Family-doctor services would also be available, and, when the labour position became easier, local authorities would provide home helps. The provision of homes for the old must have a high place in our housing programme, and tenders for more than 10,000 one-bedroom dwellings had been approved by the Minister of Health.

QUESTION TIME

Food-supplies in Germany

Mr. T. C. **Skeffington-Lodge** asked the Secretary of State for Foreign Affairs for how long he expected it to be necessary to maintain the reduction of the bread ration from 5 lb. to 3 lb. weekly in the British zone of Germany; and whether the hardship thus inflicted could be offset by stepping up supplies of other foodstuffs.—Mr. E. **Bevin** replied: The reduction which was adopted on the recommendation of the German Executive Committee as a prudent measure during a period of low stocks, and which applies to both the British and United States zones, has at present been authorised only for the first week of the ration period. It is hoped that the full issue will be made up later in May. In the past potatoes have been used when necessary to supplement shortages of grain, but these are also in short supply.

Mr. **Skeffington-Lodge**: Is the Minister aware that supplies of milk to civilians in the British zone are almost nil; and that meat, fats, and potatoes are in such short supply that the normal ration cannot be honoured?—Mr. **Bevin**: Milk has been in short supply in the British zone, but it has been possible to meet the needs of priority consumers with a fair degree of success. The position should improve with the start of the new grazing season. Difficulties in providing full rations of meat, fats, and potatoes have been largely due to the failure of the local German authorities to collect and distribute these foodstuffs equitably throughout the British and American zones.

Heavy Workers' Calories

Sir **Arthur Salter** asked the Minister of Food if he would state the calorie value of the food rations allowed to miners at home and in mining-area canteens as compared with what was allowed to other heavy-industry workers and to the general public.—Mr. **John Strachey** replied: The calorie value of the ordinary domestic (including points and personal points, but of course excluding all unrationed foods) is about 1700 calories per day. Underground miners receive for consumption at home an extra 1*s.* worth of meat and 12 bread units per week. Other heavy industrial workers receive 6 extra B.U.s per week. The calorie value of their consumption of rationed foods at home is thus increased to 2700 calories per day for underground miners and to 2100 calories for other heavy workers. Category A industrial canteens are available for use by miners and other heavy industrial workers. If they take one main meal a day they can obtain a further 800 calories, making 3500 calories a day of rationed food for miners and 2900 for other heavy workers. The average calorie intake from all foods for the nation as a whole is 2900 calories per day.

Service Sanatoria Abroad

Mr. E. **Carson** asked the Minister of Pensions whether he would consider conversations with the French authorities with a view to obtaining facilities for British ex-Service men suffering from tuberculosis to go for cures in the French Alps and other suitable places in France.—Mr. J. B. **Hynd** replied: The beneficial results of institutional treatment for tuberculosis are normally best maintained when this treatment has been given in the country in which the patient lives and works. In certain exceptional cases, treatment abroad may have a special value, and consideration is already given to such cases. I do not feel, however, that a useful purpose would be served by initiating formal conversations with the French authorities on the lines suggested.

Naturopaths and Sickness Benefits

Mr. G. **House** asked the Minister of National Insurance whether he had considered the case of a panel doctor at Birmingham influencing the non-payment of national health benefit to a patient and removing the patient's name from the list of his panel because the latter, immediately after an accident, consulted a qualified naturopath, and refused to follow the treatment the panel doctor subsequently prescribed; and if the Minister would alter his regulations to enable naturopaths to certify for National Insurance sickness benefit.—Mr. T. **Steele** replied: Sickness benefit is only payable on proof of incapacity for work. In considering whether this condition is satisfied in a particular case approved societies are not tied to the form of evidence they may accept, and my hon. Friend has been advised as to the steps the patient should take if he wishes to pursue his claim for sickness benefit.

Public Health

Smallpox

After nearly a fortnight's interval a further case was reported from Bilston, Staffs. The patient, an unvaccinated labourer, aged 69, was taken ill on April 25; a rash developed on April 29; and he was removed on May 1 to hospital, where he died the following day. Laboratory tests were positive for variola. This patient was not a contact of any known previous case. No further cases have been reported from Scunthorpe.

In New York the outbreak has been checked. Since it began, in March, 5,055,000 people have been vaccinated; this, says a *Times* correspondent, is the greatest mass smallpox immunisation of all time.

Infectious Disease in England and Wales

WEEK ENDED APRIL 26

Notifications.—Smallpox, 0; scarlet fever, 892; whooping-cough, 2044; diphtheria, 175; paratyphoid, 1; typhoid, 6; measles (excluding rubella), 7962; pneumonia (primary or influenzal), 647; cerebrospinal fever, 64; poliomyelitis, 6; polioencephalitis, 1; encephalitis lethargica, 0; dysentery, 61; puerperal pyrexia, 136; ophthalmia neonatorum, 75. No case of cholera, plague, or typhus was notified during the week.

Deaths.—In 126 great towns there were no deaths from enteric fever or scarlet fever, 1 (0) from diphtheria, 9 (1) from measles, 15 (2) from whooping-cough, 72 (9) from diarrhœa and enteritis under two years, and 21 (5) from influenza. The figures in parentheses are those for London itself.

The number of stillbirths notified during the week was 266 (corresponding to a rate of 26 per thousand total births), including 33 in London.

Obituary

ALMROTH EDWARD WRIGHT

K.B.E., C.B., M.D. DUBL., D.SC., LL.D., F.R.C.P., F.R.S.

ONE of his pupils, Carmalt Jones, has written: "For me the world consists of two kinds of people—Sir Almroth Wright and all others." That may sound a fulsome judgment, but many of those who knew and worked with Wright will understand and share it. In the early days of the century he opened a new world to them.

The impact of his ideas and personality is seen in the two accounts of him which follow—the first a memoir by Dr. Colebrook, an associate for many years, and the second an appreciation by Professor Greenwood.

* * *

He was born in 1861, in Yorkshire, of a Swedish mother—Ebba, the daughter of N. W. Almroth, governor of the mint in Stockholm and a friend of Berzelius. His father was an Irishman, the Rev. C. H. H. Wright, a considerable Hebrew scholar, who lived in his son's memory chiefly as an old man banging his fist on the table in angry denunciation of "Rome." Most of the first nine years of Wright's life were spent in Dresden and Boulogne, where his father held livings; and there no doubt he acquired some of his remarkable fluency in German and French.

For the next fifteen years he was in Ireland, first with a tutor in Belfast and later at Trinity College, Dublin, taking degrees in arts and medicine. A Grocers' travelling scholarship took him next to Germany, where he worked for several months at Leipzig, and with Kulz, at Marburg, on phloridzin. Returning to England and finding the prospect of medical practice unattractive, he launched out into law with a view to the bar. This also did not satisfy him and he accepted a clerkship in the Admiralty, presumably as a means to bread-and-butter; but as the clock struck 4 he was off to the Brown Institution, Wandsworth, where Wooldridge was working on the coagulation of blood and on diabetes, and Victor Horsley on the thyroid gland. His chiefs at the Admiralty (Carmalt Jones tells us) were in some doubt as to whether they should promote him for his ability or dismiss him for his want of diligence; but he took the choice out of their hands by accepting a demonstratorship in pathology at Cambridge. He found there, however, an atmosphere of respectability and conventionality which was uncongenial: "they did not take me at my own valuation," he told an old friend, "so I went away"—this time to Australia, where he became demonstrator in physiology at Sydney in 1889.

On his return two years later, "by the best stroke of luck that man ever had" he was offered the professorship of pathology at the Army Medical School at Netley, and here perhaps his scientific life may be said to have really begun. He found a group of young men, recently qualified and free from the cares of practice, training for the Army and the Indian medical services. Contact with Wright soon showed them that the whole of medicine was not to be found between the covers of textbooks; his adventurous mind and enthusiasm awakened them to a world of progress based on "delving below the surface of things." Leishman, Burt, George Lamb, Semple, Liston, W. F. Harvey, and Lyle Cummins were among those whose scientific careers began, and were greatly influenced by Wright, at Netley.

One of his earliest publications, based on observation of his own children and experimental work, dealt with the advantage of citrating cows' milk for infant feeding. His main interest, however, quickly became centred on typhoid fever, which had always been a scourge of armies in the field. The idea of preventive immunisation had taken shape a few years earlier in the fertile mind of Pasteur, and had already borne fruit in connexion with anthrax in cattle and hydrophobia in man. On this foundation, and on the more recent work of Haffkine with cholera in India, Wright began to build in about 1895. Pasteur's results had been obtained by the inoculation of living but attenuated cultures, or of virus-containing tissues; and Pfeiffer had shown that the blood of animals inoculated with sublethal doses of such living cultures acquired the power to dissolve and kill great numbers of cholera bacilli in the animal body. Wright, looking ahead, decided that the inoculation of living microbes to produce immunity in human beings was not going to be practicable on any large scale; and, further, he "saw with his mind" that a killed culture should be as effective as a living one. By means of new and ingenious laboratory devices, requiring many months of hard work to perfect, he was able to show that, following the inoculation of a killed typhoid culture into animals, and also into himself and his fellow-workers, the blood-serum was able to destroy living typhoid bacilli as it did in Pfeiffer's animals inoculated with living cholera. To Wright this was as good as proof that the inoculation of soldiers with killed typhoid culture would protect them against typhoid fever. But when he proposed this inoculation to the Army authorities he came up against the conservative official mind: some of those in authority disliked the novel idea of introducing microbes, whether dead or alive, into the human body, and were blinded by that dislike to all the great lessons of Pasteur's work.

There most men would have left it; but Wright saw that even bigger issues were at stake than typhoid fever—and that was big enough. The Irishman in him was aroused and he fought for his views. So powerful was the opposition that he had to resign the post he loved. Yet the fight was not lost: a supply of the vaccine was dispatched with the troops bound for the Boer War, though without a clear official blessing. Some of it was dumped overboard in Southampton Water, lest it cause disease, and was returned to Wright by the coastguards; some was inoculated in grossly excessive doses by mistake and caused severe reactions; but some was used in the doses Wright had prescribed, and statistical evidence of its prophylactic value against typhoid fever was obtained. A few years later much better evidence was derived from experience with the Army in India. On the strength of this the inoculation was adopted by the War Office as a routine procedure some years before 1914, with the result that Britain alone entered the first world war with most of her troops protected against typhoid fever. In face of an epidemic in Flanders in January, 1915, the Germans followed suit. There can be little doubt that, but for Wright's strenuous advocacy of this measure, typhoid fever would have taken an enormous toll of human life during the war of 1914–18.

Great as this achievement was, it gave Wright less satisfaction than much of his other work which resulted in "more substantial intellectual gains." "Previous work had made the circuit all ready to be completed," he would say; his was only the hand that put in the switch. Despite the remarkable success of antityphoid inoculation, his mind never became obsessed with the conventional view that prevention offers more hope than cure. In this as in some other questions, his ideas were at variance with the general trend of medical opinion during the past fifty years.

From Netley he went to India in 1898, to serve on the Plague Commission and he took a large part in the drafting of its reports. While engaged in this work he came in contact with Captain Stewart Douglas, of the Indian Medical Service, who was associated with him for many years afterwards at St. Mary's Hospital, where in 1902 Wright was appointed pathologist.

In a small underground room they embarked upon a task which was to occupy Wright's mind for forty years—the possibility of controlling bacterial diseases already in progress by the inoculation of killed cultures (vaccines). As always, he was not content to go to work blindfold, nor to judge the value of inoculation by "far-off and ambiguous clinical effects": he must know whether after each inoculation the patient's blood gave any indication that the uninfected regions of the body really had responded by an increased production of "protective substances"; he must know which doses led to such a response, and which did not; and after what interval he ought to reinoculate in order to maintain a high level of antimicrobic activity.

For all this, new technical procedures had to be developed—for the measurement of phagocytosis and of bactericidal power. The ingenious *Technique of the Teat and Capillary Glass Tube* which slowly evolved was published in book form in 1912. It was the first step—and a very considerable one—in the application of iicrotechnique to bacteriology, and must surely rank s one of his greatest contributions. Scoffers dismissed ; as just "laboratory tricks"; but Wright, with his irger vision, saw that "die Methode ist alles"; and to im these new technical procedures were essential as eking out the inadequate skill of our hands by the ontributory work of our brain." By means of them he 'as able to demonstrate the opsonic effect of serum; he far-reaching principle of autoinoculation in bacterial ifections: the bactericidal efficiency of whole blood nd of leucocytes; the influence of the antitryptic power f the serum on the rowth of microbes; nd many other 'sub-perceptible" lefence mechansms.

[From the portrait by Sir Gerald Kelly, R.A.

In this work Vright was greatly ielped by a band f men—Freeman, Iatthews, Fleming, Tohn Wells, Noon, Iayden, and others —who were soon ttracted to the St. Mary's laboratory as it expanded; nany of whom emained to build ip the Inoculation Department as it xists today. For ears before the first vorld war these men vorked far into the iight nearly every lay of the week, ounting opsonic ilms, devising new xperiments and iew technique—kept going only y their regard for 'the Old Man" as he was called even then, though he was still under fifty), and by his own never-flagging enthusiasm. About midnight someone would brew strong tea and we would knock off for a few minutes to discuss (with mighty little restraint) the day's work, or the shortcomings of the female intellect, or Wright's latest excursions in the domain of intellectual morality. With his gift for good conversation he dominated these talks, but there was always a hearing for anybody who could formulate an idea clearly: nebulous thinking got little mercy.

The 1914–18 war brought Wright's mind to grips with new problems—wound infection, gas-gangrene, shock. "Pain in the mind," which had always oppressed him until the problem he was engaged upon became sharply focused, was all the more acute during these war years, because, like Pasteur, he suffered more than most of us from the sight of suffering. To get to his laboratory at the Casino in Boulogne he had to go through wards full of wounded or sick men, and he never got used to it. Every working hour he toiled to find means to mitigate the horrors of sepsis, and in his sleep he was seldom free from them. All men's thoughts were turned at that time to antiseptics—the dream of "something out of a bottle" which would kill all the microbes in a wound. Wright alone saw that salvation was not to be had by any such short cut. He believed that antiseptics such as perchloride of mercury and carbolic killed microbes only by virtue of their being general protoplasmic poisons, and that, when introduced into an infected wound, they would inevitably be quenched by destructive combination with the greater mass of protoplasm. He saw too that we were quite in the dark as to the defensive mechanism involved in wound infections: we knew scarcely anything about the leucocytes—what conditions favoured their phagocytic activities and what hindered them; why some wounds become "corrupt," with every kind of microbe flourishing in them, while others remained clean. "To find out these essential sub-perceptible things, we must get down to the simplest elements": our unaided senses could tell us very little—apparatus and technique were necessary. The apparatus and technique did not exist, so Wright set to work again upon "laboratory tricks." Gradually he came to understand many of the things which had been obscure. He showed that some of the bacteria which commonly infect wounds, particularly staphylococci and streptococci, can grow in unaltered serum or serous exudate, but grow much more freely when the exudate or serum has been changed—e.g., by reduction of its normal antitryptic power or of its alkalinity. This reduction commonly occurred in infected war wounds; in such a "corrupt" wound, as he called it, not only could the staphylococci and streptococci grow very freely, but also a host of other organisms, such as coliform bacilli, *B. proteus*, and *Ps. pyocyanea*, most of which perished in unaltered serum or exudate. With hypertonic salt solution he sought to induce a flow of normal serum through the infected tissues towards the cavity of the wound; he regarded that flow as the essential feature of surgical drainage.

By very beautiful experiments he demonstrated in vitro the amazing capacity of healthy leucocytes to kill pyogenic cocci, and the conditions necessary for this killing. His advocacy of early closure of infected war wounds was based on these observations at his bench, and on others made by Fleming who was working with him. The surgeons were seeking to "sterilise in order to suture": Wright held that they should "suture in order to sterilise."

Some of his most illuminating work was that on gas-gangrene. To obtain the necessary anaerobic conditions he again had to devise new cultural methods. With their help it was soon made clear how the acid produced in injured muscle (or muscle deprived of its blood-supply) favoured the explosive outbreak of gas-gangrene by reducing the alkalinity of the tissue-fluid. As more muscle came to be killed by the infective process, so much acid found its way into the general circulation as to seriously deplete the body's alkali reserve, causing what Wright termed a "condition of acidæmia" which in his view was largely responsible for the patient's deterioration and death. With this process in mind he advocated treatment (when acidæmia was present) by bicarbonate or lactate of soda, and he felt justified by the clinical results (*Lancet*, 1918, i, 205). Strangely enough, very little of this work has yet found its way into textbooks, but I would hazard a guess that within the next fifty years it will be rediscovered and will be given an outstanding place in the literature of wound infections.

What I have written above touches only the fringes of his intellectual activities. In Wright's own judgment his most important work was done not at the laboratory bench, nor in his copious writings upon medical scientific problems, but in his efforts to clarify philosophical questions. "I have suffered," he once said, 'only from urticaria and philosophic doubt, and the latter was much the worse of the two." For him this work on philosophic problems was no mere intellectual diversion, as some have supposed. He did it—often with great weariness of spirit—out of a deep conviction that conditions in the rapidly changing modern world have created many problems to which the formal logic of earlier times is quite inapplicable; and because he believed that many of our social, political, and economic ills (as well as the slow progress of medicine) can only be remedied if they are approached de novo by minds illuminated by the newer knowledge of human physiology.

From 1895 he began to formulate his ideas in a study of physiological psychology which he proposed to call "The Physiology of Belief." He aimed to show how ultimately all our mental processes are bound up with physiological functions. In about 1903, I am told, the manuscript was ready for publication, but the book as he originally conceived it was never published: his mind went on unceasingly changing and improving it. It became in turn "A Dictionary of Principles," "A Treatise on Intellectual Morality," and "A System of Logic as Applied to Medicine." Only three sections of this work were issued: *The Unexpurgated Case Against Woman's Suffrage* (1913); *Prolegomena to the Logic which Searches for Truth* (1941); and *On Induction* (1943). He has, however, left a large mass of manuscript more or less ready for publication.

The characteristics of his great intellect which seem to stand out most sharply in retrospect are his "pain in the mind," which drove him on to work harder than any of the rest of us; his capacity to see where he was going and to advance steadily from one viewpoint to another; his readiness to drop a belief if new facts showed it to be false; and his indifference to any fear that he might be wrong. In his laboratory work particularly he hated loose thinking and the mere collection of isolated facts; he was always intent upon big generalisations and was not ashamed to use methods which were not completely accurate if, by repetition, they could put him on the right track. Occasionally, perhaps, they let him down.

At the age of 75, after long days of work on medical science or philosophy, he set himself to learn Russian as a recreation, and he came to read it with fair ease. Of the Bible, and of Shakespeare, Milton, Dante, and many other poets, he retained long passages learned in his youth; and he used to say that he would have given all his scientific work to have written *Romeo and Juliet*. As a public speaker and conversationalist he had few equals, agreeing with Shaw that to attract attention it is necessary to overstate the case. Sometimes, perhaps, he overdid the overstatement.

I have written of Wright only as a great intellectual force; but the report is incomplete, for in his kindliness, his essential simplicity, and all that goes to make a man lovable, he was also of no ordinary stature.

L. C.

* * *

I first saw Almroth Wright in 1906 or 1907 at a meeting of the Medical Research Club in his laboratory. I read a trivial paper which he treated with more kindness than it deserved, and after the meeting was encouraged to linger among his cronies and listen to him and Bulloch adding up the eminent men of the day and making the sum a very small integer. I had found another hero. His mere appearance, highly suggestive of Tenniel's illustration of the Lion in *Alice Through the Looking-Glass*, a kindly, dishevelled, but formidable, creature, was fascinating. Soon after that my hero-worship was deflected by a violent controversy: those were the palmy days of the opsonic index. But youthful vanity and wrath are soon dispelled by such a magician as Wright was; when I heard him speak at the presentation in 1930 his spell was as powerful as in 1907.

I cannot make any definition of a great man which would not cover Almroth Wright. I am sure at least that he was so great that one may bid him farewell with candid words.

It is easy to think of him—his likeness to Tenniel's Lion suggests it—as the dear old absent-minded German professor of sentimental comedy, whose horizon is the wall of his laboratory. Consciously or unconsciously he encouraged that belief. No professor of Shavian comedy denounced more vehemently clinicians untrained in laboratories or spoke in higher terms of science. But I suspect that Wright did not really respect laboratory-workers much more than clinicians, and that his intellectual affinity was with a Thomas Aquinas rather than with a John Hunter. In his later years he rather bored such audiences as the Medical Research Club with dialectics, and his projected treatise on logic came to be regarded as of the breed of Casaubon's key to all the mythologies in *Middlemarch*. I think, however, this was much more than a pose or a whim, that, indeed it was the kindly-old-professor attitude which had a touch of the theatrical. I should say that, like the great Schoolmen, he had far more faith in dialectics and the possibility of reaching truth by mere force of reasoning than most men of science, and that he had a considerable intellectual contempt for the ideals and methods of most of his scientific contemporaries. One of the weaknesses of the dialectical method is that it often has the appearance—even, perhaps, the reality—of treating mere "facts" rather lightly. Wright was not free from that weakness; in controversy he sometimes gave an impression of disingenuousness, of seeking to evade a real objection by means of verbalism; but this is a fault which after all can be found with Socrates himself. It was, I think, this turn of mind which impaired Wright's influence on his contemporaries. He secured personal affection but hardly inspired confidence, because his intellectual processes seemed odd to the ordinary Englishman. Like some other men of genius, he was a dangerous model.

I am of course speaking of Wright only as I knew him, and my intellectual contact with him was limited to the evaluation of results by measurement and counting. For the ostensibly precise methods of evaluation which are loosely called statistical he had an almost passionate dislike. I am sure that one element of that dislike was intrinsically sound. The notion that a person who perhaps had never done an experiment at all, and who knew nothing of the difficulties of laboratory work, should sit in judgment upon the conclusions of an adept was hateful to him. But his emotions carried him beyond that point; he condemned not only the abuse but the use of statistical method, and his principles of reasoning employed by baser spirits were quite as dangerous to intellectual honesty as anything he had stigmatised among the clinicians of forty years ago. The fact that most laboratory workers use the methods he condemned is not proof that he was on the wrong tack; he was a genius. It is proof that he was not in tune with his generation. Who was right and who wrong, some future historian will decide. We have not to wait for that historian to be sure that many of us have lost a friend.

M. G.

As a Dublin student Almroth Wright won a gold medal in modern literature and a medical travelling prize. After qualification he held a studentship at the Inns of Court in jurisprudence and Roman and international law. He was elected F.R.S. in 1906, and knighted in the same year, his work during the first world war being recognised by appointment as C.B. in 1915 and K.B.E. in 1918. An honorary fellow of the two Irish Royal Colleges, and of Trinity College, Dublin, he received honorary degrees from the universities of Dublin, Edinburgh, Belfast, Leeds, and Paris, and was an honorary burgess of Belfast. He was awarded the Hungarian prize of the International Medical Congress in 1913, the Leconte prize of the Académie des Sciences in 1913, and the gold medal of the Royal Society of Medicine in 1920, and was a corresponding member of the Institute of France. As principal of the institute of pathology and research at St. Mary's Hospital, he held a chair of experimental pathology in the University of London.

He died on April 30 at his home at Farnham Common, in Buckinghamshire, aged 85. Lady Wright, who died in 1926, was a daughter of R. M. Wilson, J.P., of Coolcarrigan, Kildare, and they had a son and a daughter.

DR. H. A. MOODY

C. E. A. B. writes: As a South Londoner may I support your tribute last week to the late Dr. Moody. Not only was he beloved by his patients but he was greatly respected by all sections of the community. His public services were many and far-reaching, and should, I feel, have received official recognition.

Notes and News

VISUAL STANDARDS FOR CANDIDATES FOR THE TEACHING PROFESSION

THE following recommendations have been made by the aculty of Ophthalmologists, at the request of the Ministry f Education :

Visual acuity, with correcting glasses, should not be less than 6/12 in the better eye.

At the age of 18 no refractive error should debar a candidate from training, but all cases in which the vision in either eye is less than 6/9 uncorrected must be referred for an ophthalmic surgeon's report and prognosis.

On reference to an ophthalmic surgeon, information is required on :

The nature and extent of the defect.
Whether it can be corrected by glasses satisfactorily for the project in view.
Whether it is progressive.
Whether the existence of the defect is likely to interfere with the candidate's efficiency as a teacher.

DISORDERS IN ATOMIC WORKERS

WORKERS at an atomic research centre in the north-west of England are alleged to have developed symptoms attributed by them to their employment. Mr. Bob Edwards, assistant general secretary of the Chemical Workers' Union, is reported in the *Daily Mirror* (April 11) as saying that the symptoms are lassitude, skin rashes, or impotence ; of 250 men at the plant, 20, he said, are complaining of impotence. The complaints are being investigated by the Ministry of Labour factory inspectorate. Meanwhile a Ministry of Supply spokesman has claimed that, in this or other plants, the only instance of disorder due to radioactivity has been one case of dermatitis ; and Prof. N. F. Mott, F.R.S., president of the Atomic Scientists Association, has stated that "methods of protection for these workers are so easily applied and so strictly enforced that it is inconceivable that the workers could be affected." Impotence and sterility of which radar workers commonly complained during the war were apparently not of occupational origin.

IODISED OIL IN RADIOLOGY

ADDRESSING the Devon and Exeter Medico-Chirurgical Society on April 17, Dr. Charles Wroth said that for the radiological demonstration of sinuses and fistulæ with iodised oil a short-necked syringe should not be used, since the catheter is liable to slip off and spray the patient's skin and clothing. Proprietary preparations of the oil are usually heavier than water, and before injection the patient should be placed so that the sinus is pointing upwards. An opaque indicator should be applied to mark the point on the skin where the sinus opens. Before films are taken the skin should be wiped clean and surplus tubing should be moved out of the way. Screening is valuable ; and at least two views, at right-angles, should be taken.

University of Cambridge

On April 26 the following degrees were conferred :

M.Chir.—W. W. Wiggins-Davies (in person).

M.B., B.Chir.—J. M. Childs, R. D. Eastham, J. H. H. Glyn, Robert Hodgkinson, D. N. Lawson, J. G. Mathewson, Edward Pringle, S. K. K. Sze (by proxy).

Royal College of Obstetricians and Gynæcologists

At recent examinations for the diploma in obstetrics the following were successful :

J. R. Ballantyne, A. C. Barthels, D. C. A. Bevis, G. R. Bourne, Kathleen A C. Bowen, J. A. Bowen-Jones, Leonard Boyars, Elizabeth C. M. Brunyate, Joyce B. Burke, H. C. Burnell, J. P. Bush, W. E. Chapman, F. J. Cockersole, D. P. Cocks, Edward Cope, G. H. R. Curnock, Alice Davies, Margaret E. Davies, J. E. Drabble, Patricia M. Elliott, Geraldine W. Everett, S. C. J. Falkman, M. R. Fell, H. J. Fisher, B. J. Frankenberg, Jean M. Frazer, G. B. Gibson, L. S. Glass, C. J. Griffin, G. N. Grose, Elizabeth M. Harper, David Hay, J. A. Henderson, G. S. Hopkins, Jean A. Horne, B. G. Isaacs, A. G. Jones, G. D. Kelly, Janet F. Kennedy, N. A. King, D. V. Latham, Christopher Lowthwaite, G. I. Louisson, Carmichael Mackie, A. T. McNeil, Betty E. A. Magill, David Mander, Edith M. Metcalfe, R. T. Michael, C. E. Miller, Albert Milton, Doreen Mitchell, Annapurna Mukherji, M. R. Nealy, G. F. Newbold, Dennis Nixon, Helen M. Noble, Margaret B. Noble, Barbara D. Oakley, A. D. Parsons, S. D. Perchard, F. C. R. Picton, E. D. Pond, K. I. Price, S. W. Price, Margaret Randell, E. N. Rees, Rachel Richards, L. F. Richards, J. G. Rountree, W. S. Russell, Ruth Sabel, T. J. Scannell, Charlotte Sommer-Hirsch, Kathleen H. Stewart, Bahman Sohrabji Surti, O. W. Sweetnam, Sheila R. Tangye, Mary E. Tighe, St. J. M. A. Tolhurst, E. F. Twiss, M. J. Twomey, W. A. Walker, Winifred I. Watson, Constance M. Watt, C. T. H. Whiteside, Roberta Williams, J. K. Wilson, Sau Haan Wong, Elizabeth Younger.

Royal Society of Medicine

Sir Edward Mellanby, F.R.S., Dr. C. M. Wenyon, F.R.S., Prof. Einar Key (Stockholm), and Prof. Naguib Mahfouz Pasha (Cairo) will be proposed for the honorary fellowship of the society on May 20.

North Middlesex County Hospital

Mr. T. H. Benians, F.R.C.S., has been appointed honorary consulting pathologist to the hospital on his retirement. Mr. Benians has been part-time pathologist to the hospital since 1925.

Royal Institute of Public Health and Hygiene

On Thursday, July 17, at 3 P.M. at the institute, 28, Portland Place, London, W.1, Dr. I. W. Magill will deliver the first Bengué memorial lecture. His subject will be a Review of Modern Anæsthesia.

War-time Decline in Dental Caries

A survey of Swedish school-children has shown that during the war the incidence of dental caries fell by about 15%. The cause of this decline is to be investigated, with special reference to changes in diet.

Institute of Social Medicine, Oxford

Mrs. Alice Stewart, F.R.C.P., has been appointed assistant director of the institute. A member of the pneumoconiosis research unit of the Medical Research Council and secretary of the industrial pulmonary diseases committee of the council, Dr. Stewart was formerly first assistant in the Nuffield department of clinical medicine at Oxford.

Tudor Edwards Memorial

A committee has been formed, under the chairmanship of Lord Horder, which will shortly launch an appeal for a memorial to the late Mr. Arthur Tudor Edwards, F.R.C.S. The members of the committee are Lord Dudley, Lord Courtauld-Thomson, Sir Max Page, Sir Stanford Cade, Dr. R. A. Young, Dr. Geoffrey Marshall, Dr. T. Jenner Hoskin, Dr. Ivan Magill, Dr. Horace Evans, Dr. Geoffrey Todd, Dr. D. T. Davies, and Mr. C. Price Thomas and Mr. F. G. Rouvray (secretaries).

Committee on Industrial Disease

The Minister of National Insurance has appointed a committee to review the policy adopted in scheduling industrial diseases under the Workmen's Compensation Acts, and to advise on the principles which should govern the selection of diseases for insurance under the National Insurance (Industrial Injuries) Act. The members include Prof. R. E. Lane, F.R.C.P., Dr. J. A. L. Vaughan Jones, Dr. E. R. A. Merewether, and Dr. Albertine Winner. Evidence should be submitted in writing to the secretary, 6, Curzon Street, London, W.1.

The Hospitals Budget

A forecast of what our hospitals will cost in the first year of the National Health Service must be prepared for inclusion in the Parliamentary estimates this autumn. The Minister of Health thinks it improbable that the new boards of governors, regional hospital boards, and hospital management committees will be in a position to submit estimates in time, and he has therefore asked the existing authorities to send him details of what their hospital has cost during the past year. This information, he adds, will not prejudice the administration of the hospital under the service, and the new authorities will later submit formal estimates for the first financial year based on their experience of working the early part of the year.

Joint Tuberculosis Council

The question of the liability of hospital and sanatorium nurses and domestics to contract tuberculosis continues to occupy the attention of this council's nursing committee. For some time it has been trying to initiate a statistical inquiry, but it has been advised that it would be necessary to study 1000 new entrants for ten years (or 2000 annually for five years) in order to get reliable data. The council have reluctantly concluded that an inquiry on this scale is at present out of the question, but the committee will neglect no opportunity of collecting useful information.

The council have protested to the Minister of Health about his announcement in Parliament that he had told the General Nursing Council of his readiness to approve rules introducing State registration for tuberculosis nurses. They hold that State registration of tuberculosis nurses should not be conditional on previous membership of the General Nursing Register.

General Medical Council

The result of the voting at the recent election was as follows:

Dr. James Brown	14,035
Dr. J. E. Outhwaite	4527
Dr. Isaac Rose	695

Dr. Brown was therefore elected a direct representative of the medical profession in England.

Emergency Artificial Respirator

Mr. E. O. Cartwright, chief engineer of the Austin Hospital for Cancer and Chronic Diseases, Melbourne, Australia, has designed a non-electric emergency respirator which works off the ordinary domestic water-supply. The apparatus can be built from a standardised design for about £70, and Mr. Cartwright will supply plans of his invention free of charge to anyone who is in need of it.

Dr. G. Carmichael Low has been appointed a member of the Committee on Bird Sanctuaries in the Royal Parks, which has lately been reconstituted.

Diary of the Week

MAY 11 TO 17

Monday, 12th

Royal College of Surgeons, Lincoln's Inn Fields, W.C.2
6.15 P.M. Mr. Julian Taylor: Cerebrospinal Rhinorrhœa.
Medical Society of London, 11, Chandos Street, W.1
8 P.M. Mr. W. E. Tanner: Guy's Worthies in the Early Days of the Medical Society of London. (Annual oration.)

Tuesday, 13th

Royal College of Surgeons
6.15 P.M. Mr. J. I. Munro Black: Nasopharyngeal Tumours.
Royal Society of Medicine, 1, Wimpole Street, W.1
5 P.M. *Experimental Medicine and Therapeutics.* Dr. J. F. Wilkinson: Folic Acid.
8 P.M. *Psychiatry.* Dr. Myer Fortes: Points of Contact between Social Anthropology and Psychiatry.
Edinburgh Postgraduate Board for Medicine
5 P.M. (Royal Infirmary.) Prof. F. A. E. Crew, F.R.S.: Biology of Polytocy.

Wednesday, 14th

Royal College of Surgeons
5 P.M. Prof. F. Wood Jones, F.R.S.: Hallmarks of Humanity. (Arris and Gale lecture.)
6.15 P.M. Mr. W. M. Mollison: Acute Otitis Media.
Royal College of Obstetricians and Gynæcologists, 58, Queen Anne Street, W.1
5 P.M. Dr. Linton Snaith: Tubal Occlusion. (Blair-Bell lecture.)
Royal Society of Medicine
5 P.M. *Proctology.* Prof. John Kirk, Prof. R. A. Willis, Mr. J. P. Lockhart-Mummery, Mr. Denis Browne: Congenital Anomalies of the Anorectal Region.
Royal Sanitary Institute, 90, Buckingham Palace Road, S.W.1
3 P.M. Dr. W. H. Bradley: Control of Smallpox.

Thursday, 15th

Royal College of Surgeons
5 P.M. Mr. Rodney Smith: Intestinal Decompression in the Treatment of Acute Obstruction. (Hunterian lecture.)
6.15 P.M. Mr. R. D. Owen: Laryngeal Stridor and Tracheotomy.
Royal Society of Medicine
5 P.M. *Dermatology.* Dr. Emil Petracek: Dermatological Experiences in Prague during World Wars I and II.
Royal Medico-Psychological Association
11 A.M. (Barnwood House, Gloucester.) Dr. E. L. Hutton and Mrs. Bassett: Prefrontal Leucotomy—Effect on Creative Personality. Dr. R. Sessions Hodge and Mrs. Y. Golla: Urethral Smears in Mental Disorder.
2.15 P.M. *Dr. W. R. Ashby: Brain Metabolism. Prof. F. L. Golla*: Electroconvulsion Therapy.
Royal Society of Tropical Medicine and Hygiene, 26, Portland Place, W.1
8 P.M. Dr. C. M. Wenyon, F.R.S.: Amœbiasis.
Institute of Laryngology and Otology, 330, Gray's Inn Road, W.C.1
11 A.M. Prof. Geoffrey Jefferson, F.R.S.: Brain Abscess.
2.30 P.M. Professor Jefferson: Posterior Fossa Tumour.
Edinburgh Postgraduate Board for Medicine
4.30 P.M. (Royal Infirmary, Edinburgh.) Dr. James Innes: Chemotherapy of Benign Tertian Malaria. (Honyman Gillespie Lecture.)

Friday, 16th

Royal College of Surgeons
5 P.M. Prof. Harry Platt: Primary Malignant Tumours of Bone.
Royal Society of Medicine
8.15 P.M. *Obstetrics and Gynæcology and Radiology.* Prof. Subodh Mitra, Mr. Charles Read, Mr. Frank Cook, Dr. G. E. Richards, Dr. G. Blomfield: Surgical and Radiological Treatment of Carcinoma of the Cervix.
Faculty of Radiologists
2.30 P.M. (Royal College of Surgeons.) Dr. G. E. Richards: Place of Surgery and of Radiotherapy in the Management of Mammary Cancer. (Skinner lecture.)
Tuberculosis Association
3.30 P.M. (26, Portland Place, W.1.) Dr. W. Santon Gilmour: Tuberculosis in China. Dr. Marc Daniels: UNRRA and Tuberculosis in Europe.

Appointments

Allan, Malcolm, M.B. Glasg., D.P.H.: M.O.H., Repton and Swadlincote, Derbyshire.
Buchanan, W. D., M.B. Glasg., D.P.H.: H.M. inspector of factories.
Crowther, D. I., B.M. Oxfd: registrar, cancer department, St. Bartholomew's Hospital, London.
Mitchell, Alfred, M.D. Lond., D.P.H.: medical superintendent, St. John's Hospital, Battersea.
Stewart, R. H. M., M.B. Lpool: medical superintendent, Tindal General Hospital, Aylesbury, Bucks.
Thorburn, A. L., M.D. Belf., D.P.H.: senior asst. school M.O., East Riding, Yorks.

Birmingham United Hospital:
Asst. physicians:
Humphreys, D. R., M.D. Birm., M.R.C.P.
Williams, G. E. O., M.D. Lpool, M.R.C.P.

Colonial Service:
Bell, P. S., M.B. Lond., F.R.C.S.E., M.R.C.P., D.T.M. & H.: director of medical services, Nyasaland.
Boyd, A. I., M.R.C.S.: M.O. (institutions), Antigua, Leeward Islands.
Daly, R. A., L.R.C.P.I.: pathologist, Tanganyika.
Fawkes, M. A., M.B. Camb.: M.O., grade B, Trinidad.
Groves, J. C., M.B. Belf.: M.O., Nigeria.
Hale, G. S., M.B. Lond., D.T.M.: S.M.O., Kenya.
Harrison, M. M., M.B. Durh.: lady M.O., Nigeria.
Haworth, James, M.B. Edin.: M.O., Nigeria.
Jones, C. M., M.B. Edin.: M.O., Nigeria.
Kerr, F. O., M.B. St. And.: lady M.O., Nigeria.
Lydon, Daniel, M.B., N.U.I.: district M.O., Windward Islands.
McKenzie, Alan, M.B. Lond., D.T.M. & H.: deputy director of medical services, Tanganyika.
Mackenzie, O. A., M.B. Glasg.: M.O., Seychelles
Mackey, J. P. P., M.B. Birm.: M.O. (pathologist), Tanganyika.
McNamara, H. E., D.R.C.O.G.: lady M.O., Tanganyika.
Murray, Douglas, M.B. St. And., D.P.H.: asst. director of medical services, Nigeria.
Ormiston, W. S., M.B. Brist., D.T.M., D.T.H.: asst. director of medical services, Nigeria.
Palmer, W. L., M.B. Durh.: M.O., British Somaliland.
Richardson, E. C., L.R.C.P.E., D.L.O., D.O.M.S.: ear, nose, and throat specialist, British Guiana.
Robinson, P. B., M.B. Dubl., D.T.M., D.P.H.: director of medical services, Northern Rhodesia.
Speirs, R. C., M.D. Edin., D.T.M.: asst. director of medical services, Kenya.
Stafford, J. I., M.B. Dubl.: M.O., Falkland Islands.
Trim, E. A., M.D. Camb., D.T.M. & H.: S.M.O., Kenya.

Examining Factory Surgeons:
Macdonald, Duncan, M.B.E., M.B. Glasg.: South Uist no. 2 district.
MacKinnon, George, M.B. Glasg.: South Uist no. 1 district.
Mason, T. O., M.R.C.S.: Dartford, Kent.
Munro, M. J., L.R.C.P.E: Swanscombe, Kent.
Pellow, R. J. N., M.C., M.B. Lond.: Luton, Beds.
Prideaux, Mary, M.R.C.S.: Warminster, Wilts.

Births, Marriages, and Deaths

BIRTHS

Bailey.—On April 28, at Taunton, the wife of Dr. K. C. Bailey—a son.

Bangham.—On May 1, in London, the wife of Dr. Alec Bangham—a son.

Carter.—On March 26, at Bournemouth, the wife of Dr. Cedric Carter—a son.

Felton.—On April 30, in London, the wife of Dr. W. F. Felton—a son.

Girdwood.—On May 3, at Edinburgh, the wife of Dr. Ronald Haxton Girdwood—a son.

Gold.—On April 25, at Bishop's Stortford, the wife of Dr. Stephen Gold—a son.

Hatton.—On April 26, at Eastbourne, the wife of Dr. P. L. S. Hatton—a daughter.

Hegarty.—On April 27, the wife of Dr. A. G. Hegarty—a daughter.

Kennedy.—On April 27, in London, the wife of Dr. D. P. Kennedy—a daughter.

Lane.—On April 29, at Maidenhead, the wife of Dr. Roger Lane—a son.

Matheson.—On April 29, the wife of Mr. Iain Matheson, F.R.C.S.—a daughter.

Reinhold.—On April 28, in London, the wife of Dr. J. D. L. Reinhold—a daughter.

Semple.—On April 28, at Aberdeen, the wife of Dr. Robert Semple—a son.

Whitehead.—On April 25, the wife of Dr. B. L. Whitehead—a daughter.

MARRIAGES

Haynes—Kirk.—On April 30, in London, W. N. L. Haynes, M.R.C.S., major R.A.M.C. (retired), to Helen Kirk, M.R.C.S.

DEATHS

Fenn.—On April 30, at Kew, Charles Edward Fenn, M.D. Durh.

Harper.—On April 30, at Barnstaple, John Robinson Harper, C.B.E., M.R.C.S., aged 79.

Joseph.—On April 26, at Llandudno, Arthur Hill Joseph, M.D. Lond., M.D. Brist., aged 83.

Leader.—On April 28, at Sheffield, Harold Leader, M.B. Lond., aged 77.

Nuttall.—On May 4, at Sandgate, Kent, Walter Wingfield Nuttall, M.D. Durh., J.P., aged 80.

Reid.—On April 30, in London, John McGregor Hartley Reid, M.B. Aberd., D.P.H., aged 55.

Wright.—On April 30, at Farnham Common, Sir Almroth Wright, K.B.E., C.B., M.D. Dubl., F.R.C.P., F.R.S., aged 85.

CHILD GUIDANCE IN OLD AGE

J. M. MACKINTOSH
M.D. Glasg., F.R.C.P., F.R.C.P.E.
PROFESSOR OF PUBLIC HEALTH IN THE UNIVERSITY OF LONDON

DURING the past twenty years or so we have heard a great deal about child guidance, and an interesting technique has been developed for the treatment of behaviour problems. The child-guidance team, led by psychiatrist, psychologist, and psychiatric social worker, has made valuable contributions to both research and therapy. Much has been learned about the causes of antisocial conduct in children, and this knowledge is of wide pplication to the general care of children.

So far, little attention has been given to the behaviour roblems of old age, in spite of an increasing devotion o the medical and social care of the aged and infirm. t is common knowledge that many old people become ust as "difficult" as troublesome children, but we are hy of facing the problem squarely. The reasons for our iffidence are clear enough: the dignity of age, the long radition of reverence sanctioned by creed and custom, the authority which the old exercise over the young, the reputed wisdom of experience—these and other qualities tend to prevent us from studying and analysing some less desirable features. It is embarrassing even to talk about the egoism, the obstinate clinging to power, the petulance, the readiness to take offence, and the utter childishness which sometimes mar the grave countenance of age. We have around us a number of noble ruins which deserve preservation, but at the same time require to be trimmed and kept in order.

It is much easier to criticise what we have been than to look with clear, discerning eyes at what we may become. As we grow older, self-criticism tends to become somewhat blunted, and the comic spirit fails us when we take the stage as elders of the people. In a characteristic passage Meredith[1] proposes a useful test:

> "You may estimate your capacity for comic perception by being able to detect the ridicule of them you love, without loving them less; and more by being able to see yourself somewhat ridiculous in dear eyes, and accepting the correction their image of you proposes."

Elderly folk, especially men, find difficulty in accepting that correction. They hate to be comic figures; their minds are not quickened through laughter.

> "You will find learned men undoubtedly, professors, reputed philosophers, and illustrious dilettanti. They have in them every element composing light, except the Comic. They read verse, they discourse of art, but their eminent faculties are not under that vigilant sense of a collective supervision, spiritual and present, which we have taken note of. They build a temple of arrogance; they speak much in the voice of oracles. . . . Insufficiency of sight in the eye looking outward has deprived them of the eye that should look inward. They have never weighed themselves in the delicate balance of the Comic idea so as to obtain a suspicion of the rights and dues of the world: and they have, in consequence, an irritable personality."

TREATMENT AND PREVENTION

The behaviour problems of the aged are sometimes acute and distressing; yet they are seldom tackled seriously, unless the victim is suffering from a blatant dementia. It has been shown recently that the aged and infirm respond well to careful physical treatment, and there is reason to believe that the response to sound psychological treatment would be equally good. It has even been suggested that a special school, preferably residential, might be set up for the re-education of difficult ancients. The word "school" may sound queer, but the idea behind it is not in the least fantastic. Many elderly folk would profit immensely, both physically and mentally, by training for an occupation suitable to their age and capacity especially when the alternative is to hang grimly on to a job that has become too heavy—or to rust unburnished.

A fair trial might be given to preventive measures. One method is to write a letter to one's own old age, to be opened on the sixty-fifth birthday. I cannot remember accurately the details of my letter, deposited these ten years with the Westminster Bank, but the gist of it is as follows:

> "My dear Mackintosh,
>
> I hesitate to call you by your Christian name, as I hardly know you. All the same, I think you may profit by a few words of friendly advice. Certain undesirable tendencies in your character and outlook are already apparent and I have little doubt that they will become more marked as you grow older, just as they did with your father. (Here follow some intimate details with which I need not trouble the reader.)
>
> "The main thing to remember, however, is that you are now 65 and on the point of retirement. For heaven's sake retire, and do not persuade yourself that you are a special case. If you have kept mind and body active, a whole world of new interests lies before you; if not, you have no business to cling to office, or indeed to any of the voluntary or other services you now undertake. Clear out. Do not rationalise by saying that you 'want to see this thing through.' That is just another barnacle argument: what you really want is to cling. . . ."

And so the letter ran on. The real question is whether it will be effective, or merely cast aside with an indulgent smile. There is no more reason to suppose that age will take advice from youth than that the young will accept the counsel of their elders. It is in fact less likely, for the law of libel prevents us from saying what we think about our elders, and their contemporaries are reluctant to interfere, because they themselves are vulnerable.

Throughout the centuries there has been much philosophical discussion about old age, and literature and the arts are rich in description of its beauty and serenity:

Sophocles, Plato, Socrates,
Gentlemen,
Pythagoras, Thucydides,
Herodotus and Homer,—yea,
Clement, Augustin, Origen,
Burnt brightlier towards their setting-day,
Gentlemen.[2]

Sympathy with the sorrows of age has not been wanting. "Lights of infinite pity star the grey dusk of our days"[3]; but George Russell wrote in the same poem:

If our thought has changed to dream, our will unto desire,
As smoke we vanish though the fire may burn.

APPROPRIATE WORK

The application of medicine to the problems of old age should be considered in a serious spirit. We should be able to establish principles of treatment for behaviour difficulties in the elderly, especially at the present time when they are forming an increasingly large proportion of the community. In our pressing economic stresses we cannot afford to waste their talents and their working capacity; nor can we allow them, for sentimental or other reasons, to retain positions for which they are no longer fitted—mentally or physically, as the case may be. Many ageing people might welcome a system of psychological selection of the kind which was so successful in dealing with Army recruits, a job-analysis to give encouragement, and a prospect of usefulness in the great team-work that lies before us in this country. A relatively simple analysis would show that there are many occupations particularly suitable for the men and women who have reached the age of retirement, according to their intelligence and experience. For many the curse of oneliness could be exorcised, and the days and years renewed with vigour and interest. The selection procedure should of course be positive, based on capacities and not on disabilities. In dealing with the disabled this system has been effective, indicating the type of work that the applicant can do rather than setting out the range of jobs for which he is unfit.

---

[1] George Meredith. Essay on Comedy.

[2] Thomas Hardy. An Ancient to Ancients.

[3] Poems by Æ (George Russell).

The whole subject is a delicate one in which we have to tread warily; but it is urgent and serious enough to be regarded with clear eyes, unclouded by either misplaced frivolity or befuddled sentimentality:

> I have not writ this letter of divining
> To make a glory of thy silent pining,
> A triumph of thy mute and strange declining.

So spoke Alice Meynell in "A Letter from a Girl to her own Old Age"; and the neglected Browning put the whole matter in a nutshell thus:

> And the whole is well worth thinking o'er
> When autumn comes: which I mean to do
> One day, as I said before.[4]

BIOCHEMISTRY OF INFLAMMATION

VALY MENKIN
M.D. Harvard
ASSOCIATE PROFESSOR OF EXPERIMENTAL PATHOLOGY,
TEMPLE UNIVERSITY, PHILADELPHIA

INFLAMMATION is a fundamental process in higher animals, which involves lymphatics, blood-vessels, and the locally affected tissue, and is initiated by a disturbance in the fluid exchange. The normal capillary filtration equilibrium is upset, one important change being an increase in capillary permeability, which is readily demonstrable by the seepage of material introduced into the circulation. Diazo dyes (such as trypan blue), ferric chloride, graphite particles, and bacteria will readily concentrate from the circulation into acutely inflamed foci (Menkin 1940a). Since this increased capillary permeability is an initial stage of inflammation, knowledge of its mechanism is essential to the understanding of subsequent developments.

LEUKOTAXINE

The early work of Lewis (1927) postulated that the increased capillary permeability in inflammation was primarily due to the presence in weal fluid of a hypothetical H-substance, which was presumed to be histamine. I have not been able to confirm this (Menkin 1936); in fact, the following observation suggests the liberation into inflammatory exudate of a substance which seems to have no direct biological relation to histamine (Menkin 1938a).

If inflammatory exudate is injected into the normal skin of a rabbit, and this is immediately followed by the intravenous injection of trypan blue, the dye rapidly accumulates in the treated area of the skin, indicating the probable presence in the exudate of a factor which increases permeability. This factor is absent from blood-serum, and the reaction is not elicited by physiological saline. The active substance, "leukotaxine," is thermostable and diffusible through a 'Cellophane' membrane. By treating inflammatory exudate with pyridine and then acetone to remove proteins a crystalline-like active material can be recovered in a butyl alcohol mother liquor. Leukotaxine can also be precipitated by treating the exudate with ammonium sulphate to half saturation.

Various methods have been devised to extract this active factor (Menkin 1940a). The present method, somewhat modified from the original scheme, is as follows:

Exudate
Pyridine (1 : 1)
Centrifuge
Supernatant
Acetone (1 : 1)
Supernatant
Dried on steam bath at about 70°C
Butyl alcohol (0·5 : 1 part of acetone supernatant)
Stir for 24 hours
Concentrate to $^1/_{10}$ vol. on steam bath at about 70°C
Partially dry by freezing with CO$_2$ snow
Crystalline-like material (leukotaxine)

The active factor, leukotaxine, is biuret-negative but ninhydrin-positive. The Millon test is negative, but the Adamkiewicz colour-reaction for the indole nucleus is positive. The xanthoproteic test for the phenyl group is likewise positive. Chemically, leukotaxine seems to be a relatively simple polypeptide to which there may be attached an unidentified prosthetic group, but this has not yet been established. Studies on the enzymatic effect of crystalline trypsin on an otherwise inert serum albumin or whole serum support the view that the biological activity may largely be confined to the peptide linkage (Menkin 1938b). Finally, amino-nitrogen measurement before and after hydrolysis indicates the possibility that the active principle be a relatively simple peptide.

Leukotaxine not only increases capillary permeability but also induces the migration of polymorphs through the capillary walls. This chemotactic property can be demonstrated both in vitro and in vivo (Menkin 1940a). The liberation of leukotaxine is therefore a reasonable explanation of the increased capillary permeability and migration of leucocytes in inflammation. The yield of leukotaxine from inflammatory exudates is relatively small, but its activity is well marked. Workers in England have confirmed the presence of leukotaxine in such exudates (Cullumbine and Rydon 1946), using a somewhat different technique of extraction. Further, these workers have pointed out the abundance of leukotaxine in the succus entericus of the rabbit. In Japan, Minami and Inugami (1940) have also found leukotaxine in inflammatory exudates.

Recent studies indicate that leukotaxine or a similar substance can sometimes be recovered from various other body fluids, such as those in ovarian cysts, craniopharyngiomata, and gliomata (astroblastomata). It is conceivable that the formation of fluid in these pathological conditions is partly due to the local production of leukotaxine.

Increased capillary permeability, caused by the liberation of leukotaxine, allows the free passage of plasma proteins from the circulation into the extracapillary spaces. Fibrinogen is converted into fibrin, with the release of thrombokinase, after injury to cellular structures. A network of fibrin is formed in tissue distended with œdema, and lymphatic channels become plugged with fibrin. This early lymphatic obstruction prevents the ready dissemination of material or micro-organisms from a focus of acute inflammation. This discovery adds to our understanding of the rôle of inflammation in immunity (Menkin 1938c).

LEUCOCYTOSIS-PROMOTING FACTOR

Leukotaxine is responsible for the local migration or diapedesis of leucocytes to the site of injury; it does not affect the number of circulating leucocytes. Yet leucocytosis often accompanies inflammation or infection. Now, injection of inflammatory exudate from an animal or a man with leucocytosis into the blood-stream of an otherwise normal dog or guineapig can cause leucocytosis. It is reasonable to conclude that the inflammatory exudate contains a leucocytosis-promoting factor liberated by injured cells (Menkin 1940b, Menkin et al. 1946). This leucocytosis-promoting factor (L.P.F.) has, indeed, been found; it is non-diffusible and thermolabile, and resembles a protein. It is obtained from the exudate by treating it with ammonium sulphate to half saturation after removal of the euglobulin fraction (Menkin 1940c 1946a, Menkin and Kadish 1943), and seems to be either a pseudoglobulin or at least closely associated with that fraction of the exudate. Unpublished studies in collaboration with Gerald Cooper, of Duke University school of medicine, using a Tiselius apparatus, indicate that the L.P.F. is closely associated with the alpha globulins of inflammatory exudates.

The L.P.F. induces not only a discharge of immature leucocytes from the bone-marrow but also hyperplasia of granulocytes and megacaryocytes in the bone-marrow (Menkin 1943a). The presence of the L.P.F. is demonstrable only in the serum of an animal with acute inflammation, and not in a normal animal's blood-serum. The liberation of the L.P.F. into inflammatory exudate and its absorption into the circulation offer a reasonable explanation of the leucocytosis associated with inflammation.

The apparent and essential non-antigenicity of the L.P.F. (Menkin 1944) and its property of stimulating the production of leucocytes in the bone-marrow suggest definite clinical applications, especially since it is well known that the prognosis of numerous infections depends largely on the number of circulating leucocytes. Recent studies at Duke University have demonstrated that the intravenous injection of canine L.P.F. into human beings is both innocuous and effective. The doses used ranged from 18 to 230 mg. The injection of the material into human beings is followed by a discharge of immature granulocytes into the circulation (Menkin 1946a). The clinical implications of these studies are obvious. Already a patient with a persistent leucopenia has responded favourably for short periods to the intravenous injections of relatively low doses of the L.P.F. Similar studies are now in progress.

NECROSIN

Inflammation is a manifestation of severe cellular injury. Neither leukotaxine nor the L.P.F. per se can reproduce that injury. The injury seems to be due to the liberation of a substance located in or associated with the euglobulin fraction of the exudate, particularly when the exudate has an acid reaction when withdrawn from the site of inflammation. This substance has been termed necrosin (Menkin 1943b).

The injection of necrosin into the skin of a rabbit is followed within several minutes by swelling and fusion of the collagenous bundles; this type of response cannot be induced by the injection of the euglobulin fraction of normal blood-serum. After a longer interval inflammation develops, with intense redness, œdema, and superficial necrosis. An abundance of leucocytes may be found in such areas. Lymphatics are occluded by fibrin, and blood-vessels may be thrombosed. The euglobulin fraction of normal blood-serum does not induce lymphatic obstruction, which in turn is evidence of severe damage.

The intravenous injection of necrosin may be followed by the formation of fluid in the chest cavities or by hæmorrhages all along the gastro-intestinal tract; but more constantly focal necrosis of the liver develops. Sometimes, after several intravenous injections of necrosin, one finds a considerable deposition of fat in the liver; at other times the hepatic tissue is strewn with large amounts of glycogen. The injection of necrosin into the blood-stream is accompanied by a relatively small rise in the blood-sugar level (Menkin 1946b), averaging about 20% after a single injection. The kidneys may also show foci of leucocytic infiltration as a result of the introduction of necrosin into the circulating blood. Such infiltrations are found interspersed among tubules that show fuzziness of their epithelial lining and vacuolation of the cells. The glomeruli at times have a curious colloid-like material occluding the capsular space of Bowman.

Necrosin is absent from normal blood, but may be present in that of an animal with inflammation (Menkin 1943b). The fact that necrosin penetrates from an area of injury into the blood-stream and then damages essential organs may prove of clinical significance in focal infections.

Necrosin is also lethal to mice, in contrast with other protein fractions of inflammatory exudate. Finally, in collaboration with Frederick Bernheim, of Duke University, it has been found that necrosin exerts a mild proteolytic effect.

PYREXIN

It was observed that the whole euglobulin fraction of inflammatory exudate would not only reproduce the cellular injury of inflammation but also, when injected intravenously, would lead to fever and leucopenia. This whole euglobulin fraction was at first named necrosin (Menkin 1943b), and its presence in inflammatory exudate was confirmed by Smith and Smith (1945) and Tanturi et al. (1945). Subsequently, however, it has been found that, whereas necrosin is thermolabile, its components that induce fever and leucopenia are thermostable.

It was soon recognised that the euglobulin fraction of the exudate had a component insoluble in the presence of electrolytes. By differential solubility this component was dissociated from a true euglobulin which in turn behaved like necrosin, damaging the skin of rabbits and proving lethal to mice. After purification necrosin was found to be essentially non-pyrogenic. It is true that at times it is difficult to obtain clear-cut separation between the injury factor (necrosin) and the pyrogenic component, which has been termed "pyrexin." The intravenous injection of pyrexin induces fever in the rabbit (Menkin 1943c, 1945). It is therefore reasonable to suppose that its absorption is the cause of the fever that accompanies inflammation.

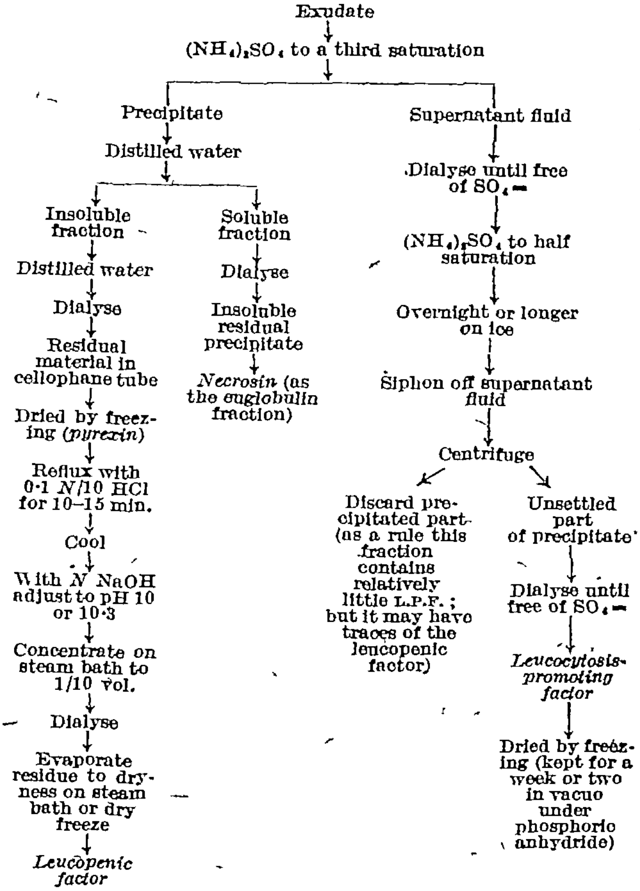
Pyrexin is thermostable. Boiling does not essentially alter its activity. It seems to be excreted, at least in part, in the urine. Its exact chemical composition is unknown. The biuret reaction is positive only in minute trace. The xanthoproteic test is positive. The ninhydrin test is positive, except when pyrexin is recovered from urine. Pyrexin gives a positive Molisch test. Observations made in collaboration with Frederick Bernheim, indicate that pyrexin may be a relatively simple polypeptide. In view of the constant presence of a carbohydrate grouping (as indicated by the positive Molisch test), pyrexin may prove to be a glycopeptide.

LEUCOPENIC FACTOR

As mentioned above, the whole euglobulin fraction of inflammatory exudate induces leucopenia. Vomiting, diarrhœa, and general apathy are also not infrequent. Studies have been undertaken to determine, if possible, the mechanism of leucopenia, which often accompanies inflammation. An inflammatory exudate, particularly if acid on withdrawal, tends to induce a transitory leucopenia when injected in a normal dog. The same result is obtained by injecting the whole euglobulin fraction of the exudate. There is evidence that this effect is not due to necrosin but to a leucopenic factor closely, but apparently not invariably, associated with pyrexin. This leucopenic factor seems to be a polypeptide (Menkin 1946c). The leucopenia appears to be due to a trapping of the leucocytes in lungs, liver, and spleen. This accumulation of leucocytes may help to explain the acute enlargement of the spleen in inflammatory conditions (Menkin 1946d).

COMMENTS

The leucocytosis-promoting factor, necrosin, pyrexin, and the leucopenic factor can be recovered from an inflammatory exudate as follows:



Exudate
$(NH_4)_2SO_4$ to a third saturation
Precipitate
Distilled water
Insoluble fraction
Distilled water
Dialyse
Residual material in cellophane tube
Dried by freezing (*pyrexin*)
Reflux with 0·1 *N*/10 HCl for 10–15 min.
Cool
With *N* NaOH adjust to pH 10 or 10·3
Concentrate on steam bath to 1/10 vol.
Dialyse
Evaporate residue to dryness on steam bath or dry freeze
Leucopenic factor
Soluble fraction
Dialyse
Insoluble residual precipitate
Necrosin (as the *euglobulin* fraction)
Supernatant fluid
Dialyse until free of $SO_4^{=}$
$(NH_4)_2SO_4$ to half saturation
Overnight or longer on ice
Siphon off supernatant fluid
Centrifuge
Discard precipitated part (as a rule this fraction contains relatively little L.P.F.; but it may have traces of the leucopenic factor)
Unsettled part of precipitate
Dialyse until free of $SO_4^{=}$
Leucocytosis-promoting factor
Dried by freezing (kept for a week or two in vacuo under phosphoric anhydride)

These biochemical substances present in inflammatory exudate help to explain some of the major sequences in the development of inflammation. There are doubtless other factors to be discovered. For instance, it has been shown that any injured cell is potentially gluconeogenetic, a fact which may partly explain why inflammation exerts a bad influence on diabetes (Menkin 1941a, 1943d). It is also conceivable that the end-stage of inflammation or repair may depend on the liberation of one or more growth-promoting factors at the site of injury (Menkin 1941b).

SUMMARY

The altered chemistry of injured cells liberates into the inflammatory exudate various biochemical substances which are responsible for the clinical features of inflammation.

Five of such substances are described: leukotaxine, a leucocytosis-promoting factor, necrosin, pyrexin, and a leucopenic factor.

Leukotaxine increases local capillary permeability diapedesis of leucocytes.

The leucocytosis-promoting factor induces a discharge of immature leucocytes from, and hyperplasia of granulocytes and megacaryocytes in, bone-marrow.

Necrosin exerts a necrotic effect on local cells and, after absorption into the blood-stream, on distant organs.

Pyrexin induces fever.

The leucopenic factor induces leucopenia, the leucocytes apparently being trapped in lungs, liver, and spleen.

PHYSICAL BASIS OF CONTINUOUS INTRAVENOUS INFUSIONS

J. N. WALTON
M.B. Durh.
HOUSE-PHYSICIAN, CHILDREN'S DEPARTMENT, ROYAL VICTORIA INFIRMARY, NEWCASTLE-ON-TYNE

THE administration of intravenous fluid is now a common procedure, and on occasions its use is a clinical necessity for correcting the dehydration and circulatory failure which accompany many diseases of infancy and early childhood. A measure of agreement has been reached on the nature and amount of fluid required in different conditions (Coller and Maddock 1935, Arnott and Young 1942), but in view of the technical difficulties and the hazards of intravenous infusions it is surprising that so little attention has been given to the physical factors that govern and affect them. Those who watch over the "drip" know how capricious its behaviour may be, and such apparent caprice may be a serious matter for the infant, who may be "drowned" by a moderate excess of intravenous fluid. Is the behaviour of the "drip" due mainly to varying factors in the patient, or to the essential nature of the apparatus used? This paper describes laboratory experiments designed to furnish an answer to the second question and suggests some of the practical measures which follow.

The apparatus (fig. 1) used in the experiments consists of two reservoirs *a* and *b*, a standard interceptor *c*, two adjustable clips *d* and *e* for rubber tubing, a Bateman needle *f*, and a measuring cylinder *g*. Except for the measuring cylinder, which was necessary for these experiments, the apparatus was the standard instruments used in the children's department at this hospital. The graduated 100 c.cm. cylinder *b* is a particular feature of this apparatus. It allows accurate measurement of the quantity of fluid administered, and it is also a safety device, for, even if the drip ran more quickly than was expected, no more than 100 c.cm. of fluid would run through the apparatus.

THE EXPERIMENTS

If the times taken to give a known volume of fluid at varying rates are in indirect proportion, it should be possible to calculate these rates once a single reading has been taken. This will only hold good, however, if the size of each individual drop remains constant in every case. Several factors may affect the size of drop: (i) the nozzle diameter of the interceptor, (ii) the viscosity and specific gravity of the fluid, (iii) the fluid pressure above the nozzle, (iv) the rate of flow, and (v) the resistance in the needle and the circulation beyond. If experimentally it is possible to keep any four of these factors constant, it should be possible to decide which among them affects the size of the individual drop, and to determine a series of standard rates of flow for the administration of different volumes over different periods of time.

All the following experiments were carried out in the same room with the same apparatus, and the length of rubber tubing and the height of the reservoir from the floor were kept constant.

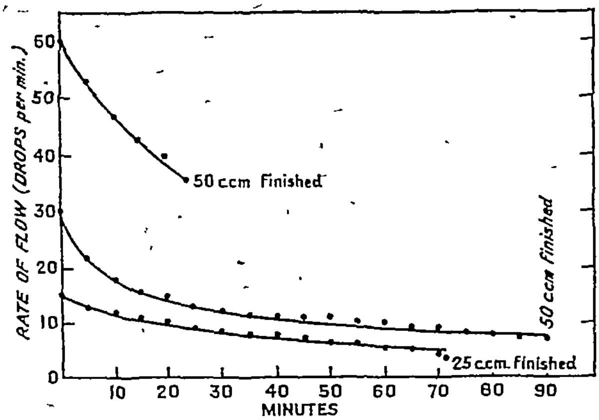

Fig. 2—Decrease in rate of flow.

Experiment I

Exactly 50 c.cm. of fluid (*N*/5 saline + 4·1% dextrose) was poured into *a*, and *b* was filled with similar fluid up to about 1 in. above the level *h*. This level *h* was previously fixed at the level of 50 c.cm. of fluid in *b*. While the flow was controlled with tap *e*, the tubing down to *f* was filled with fluid and the rate of flow was adjusted to 60 drops per min. As soon as the level in *b* had reached *h*, the needle *f* was transferred to another measuring cylinder: the time was noted, and fluid was dropped in from *a* so as to keep the level in *b* constant at *h*. The fluid was left to flow through the apparatus until *a* was empty, and therefore 50 c.cm. had flowed through the apparatus. This was checked by the reading in *g*, which was 50 c.cm. The time at which this occurred was noted exactly. Throughout the experiment the rate of flow was checked every 5 min. by counting the number of drops in 60 sec. The experiment was repeated with different rates of flow.

The results (fig. 2) suggest that, though the drip was initially adjusted for a constant speed and all the other factors remained constant, the rate of flow steadily and appreciably diminished. The apparatus was then carefully overhauled and the experiment repeated. The results were identical.

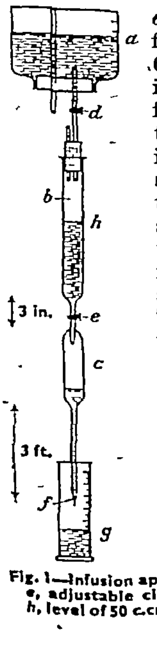

Fig. 1—Infusion apparatus: *a* and *b*, reservoirs; *c*, interceptor; *d* and *e*, adjustable clips; *f*, Bateman needle; *g*, measuring cylinder; *h*, level of 50 c.cm. of fluid in *b*.

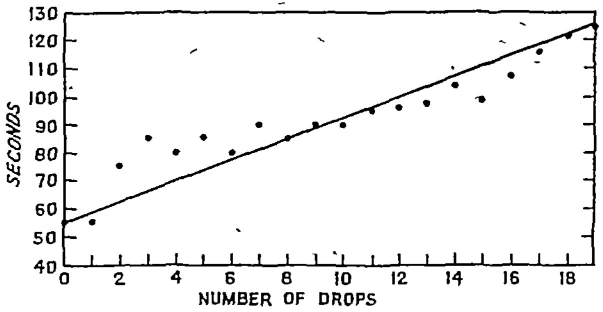

Fig. 3—Increase in time taken for each drop.

Experiment Ia

The drip was then set flowing as slowly as possible, and the exact length of time required for each drop was measured (fig. 3). The time taken for each drop gradually increased, and eventually the flow stopped. When the apparatus was cleaned and filled with water a similar result was obtained.

It is clear from these observations that, with the apparatus described and with fixed amounts of water or of saline-dextrose, the drip, when adjusted to flow at a given speed, slows down and eventually stops. The practical corollary is that, if a constant rate of flow is to be maintained, frequent supervision and readjustment will be necessary.

Experiment II

The initial experiment was repeated, the rate of flow being kept constant by frequent adjustment. The times taken for a given volume to pass at different rates are given in table I. It appears from this table, which shows a steady increase in the number of drops per c.cm. and hence a steady decrease in the size of the drop as the rates get slower, that the rate of flow affects the size of the drop.

From the results in table I obtained by practical observations it is possible to calculate the time taken for multiples of the amount used (50 c.cm.) to pass through the apparatus. Results obtained in this manner are shown in table II and fig. 4.

TABLE I—EFFECT OF CONSTANT RATE OF FLOW ON SIZE OF DROPS

Volume of fluid	Rate of flow (drops/min.)	Time taken (min.)	Drops/c.cm.
50 c.cm.	90	11	20
	60	18	21
	30	38	23
	15	78	23
	10	120	24
	5	245	25
	1	1275	26

Experiment III

Besides the variation of the size of drop with the rate of flow, it is necessary to determine the relation between the size of drop and the diameter of the nozzle of the interceptor, using the same saline-dextrose solution and the standard volume and speed.

Experiment I was repeated with (i) interceptor B in which the diameter of the nozzle was much smaller than the standard A (diameter 2·25 mm.), and (ii) four interceptors C, D, E, and F (diameter 2·0–2·25 mm.) regarded as identical with A and taken as random samples from the hospital store.

Table III shows, as expected, that the volume of the drop is affected considerably by variations in the diameter of the nozzle of the interceptor. With interceptor A as the standard, a factor can readily be calculated

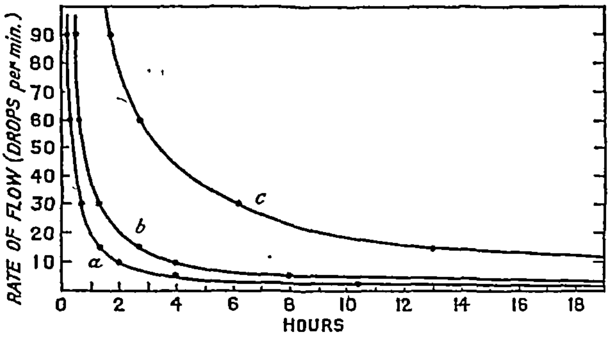

Fig. 4—Rate of flow necessary to infuse a given volume of fluid in a given time; *a*, graph for 50 c.cm. of *N*/5 saline plus 4·1 % dextrose; *b*, graph for 100 c.cm.; *c*, graph for 500 c.cm.

for each of the others and the times in table II modified accordingly. This is unnecessary in practice, provided the interceptors in all infusion sets have a common diameter or at least show no greater variation than C to F in the experiment. Accepting this range, table II can be modified as shown in table IV.

Experiment IV

The standard experiment was now repeated with human blood and blood-plasma and gave the following results:

Fluid	Time (min.) taken by 50 c.cm. at— 30 drops per min.	60 drops per min.
Saline-dextrose	38	18
Blood	50	21
Plasma	48	20

Therefore blood takes about 5/4 times, and plasma 6/5 times, as long as saline-dextrose.

The character of the fluid clearly affects the size of drop, the more viscous fluids, blood and plasma, having smaller drops and slowing more quickly than saline-dextrose. In fact, if blood was set flowing at 10 drops a minute it

TABLE II—APPROXIMATE TIMES TAKEN AT DIFFERENT RATES OF FLOW FOR DIFFERENT VOLUMES OF $N/5$ SALINE + DEXTROSE TO PASS THROUGH APPARATUS

Vol. of fluid (c.cm.)	Rate of flow (drops/min.) 90	60	30	15	10	5	1
50	11 min.	18 min.	40 min.	80 min.	2 hr.	4 hr.	21¼ hr.
100	22 min.	35 min.	80 min.	160 min.	4 hr.	8 hr.	42 hr.
200	45 min.	70 min.	2½ hr.	5¼ hr.	8 hr.	16¼ hr.	85 hr.
500	1¾ hr.	2¾ hr.	6¼ hr.	13 hr.	20 hr.	40 hr.	9 days

ppeu very quickly. To find the times taken at given es for these fluids to pass through the apparatus the ues given in table IV should be multiplied by 5/4 blood and 6/5 for plasma. These factors will apply all volumes since the physical nature of the fluid nains constant.

xperiment V

The standard experiment was fi… The reserv… ifferent heads of fluid in *b*. The reserv… an…peated with bove the 0 mark in *b* with saline-dextrose When the level reach…ed to oing at 60 drops a minute. he needle *f* was transferred to a fresh measuring cylinder, and the times taken for the first, second, third, and fourth amounts of 20 c.cm. to flow through were noted. The rate was constantly adjusted to 60 drops a minute, and the fact that [illegible] flow through while the level fell from [illegible] another was checked by taki[illegible] cylinder *g*. [illegible] and so the [illegible] too.

Thus the level [illegible] head of pressure [illegible]

The time taken for the four separate volumes was identical; hence the head of pressure in *b* does not materially affect the size of the drop. However, the rate of flow needed adjustment more often to 60 drops a minute at the lower levels; so it seems probable that at lower pressures the drip tends to slow more readily.

It must be remembered, however, that raising or lowering the cylinder *b* in relation to the Bateman needle makes an appreciable difference to the rate of flow. This variable factor can be eliminated by making the length of each drip apparatus that of the standard; and, if in each case the cylinder is raised to the maximum above the needle, the results given in the tables and figures will hold good.

COMMENT

It is clear that there is an inherent tendency in the infusion system described for the rate of flow to slow down. This means in practice that the amount of fluid reaching the patient in the prescribed period may be far less than the estimated requirement, leading to a continuance of the dehydration or circulatory failure. On the other hand, if this difficulty is overcome by the use of high rates of flow, excessive water retention with dangerous or even fatal results may follow. To avoid these difficulties the following suggestions are made:

TABLE III—EFFECT OF DIAMETER OF NOZZLE OF INTERCEPTOR ON VOLUME OF DROP

Type of interceptor	A	B	C	D	E	F
Time (min.) for 50 c cm. to pass at 60 drops/min.	18	25	20	18	20	18

A, standard; B, small diam.; C, D, E, F, considered similar to A.

(1) An adequate number of standard infusion sets identical with the one used in these experiments should be provided, so that the figures given in table IV and fig. 4 can be applied.

(2) The rate of flow should be frequently adjusted to the initial figure.

(3) The amount of fluid given should be accurately recorded, special charts for this purpose being provided and kept with the case-notes.

If the nurse is told how often the 100 c.cm. cylinder should be refilled, and with what fluid, and if the rate of flow required to give this quantity is noted from fig. 4 there should be no danger of inadequate or excessive therapy.

Practical experience shows, however, that the problem is not confined to the apparatus. Variable factors arising in the patient are also operative. This aspect has been carefully investigated by Pugsley and Farquharson (1944), who found that the main human and other factors influencing the efficiency of flow were:

TABLE IV—LIMITS OF VARIATION IN TIMES TAKEN AT DIFFERENT RATES OF FLOW FOR DIFFERENT VOLUMES OF SALINE-DEXTROSE SOLUTION TO PASS THROUGH APPARATUS

Vol. of fluid (c.cm.)	Rate of flow (drops/min.) 90	60	30	15	10	5	1
50	11-12½ min.	18-20 min.	40-45 min.	80-90 min.	2-2¼ hr.	4-4½ hr.	21-24 hr.
100	22-25 min.	35-40 min.	80-90 min.	2¼-3 hr.	4-4½ hr.	8-9 hr.	42-48 hr.
200	45-50 min.	70-80 min.	2½-2¾ hr.	5¼-6 hr.	8-9 hr.	16-18 hr.	85-95 hr
500	1¾-2 hr.	2¾-3 hr.	6¼-7 hr.	13-14 hr.	20-23 hr.	40-47 hr.	9-10 days

(1) The size of the vein at the site of the infusion.

(2) The nature of the infusion (some fluids, notably serum and plasma, produce vasoconstriction).

(3) The temperature of the fluid as it enters the vein.

(4) The pressure of fluid.

In infants these and other potential resistances are often encountered and can be overcome in various ways.

It is not my purpose to describe the technique of venesection in infants, though this has a great bearing on the efficiency of the drip; nor is it to discuss in detail the further potential resistances which arise, but the following facts may be usefully noted. The internal saphenous vein at the ankle has been used routinely as first choice. The effective immobilisation of the limb has been secured by a simple posterior plaster splint made immediately after venesection, and applied with the foot in plantar flexion. The upper end of this splint should reach well above the popliteal fossa, and tight bandaging must be avoided. The leg is then raised on a pillow. Heat from a hot-water bottle round the lower part of the tubing is often helpful. Should initial vasoconstriction be severe it can be overcome by positive pressure applied with a syringe and three-way tap set introduced between the lower end of the tubing and the Bateman cannula.

SUMMARY

In the standard infusion system described the rate of flow tends to slow down and stop, though no cause for this could be found.

The size of each drop varies with the rate of flow, the diameter of the interceptor nozzle, and the viscosity of the fluid used. It is not materially affected by the head of pressure in the secondary reservoir.

The practical applications in the ward are briefly described.

I wish to thank Prof. J. C. Spence for his encouragement, Dr. Brenda Morrison for initial suggestions, Dr. Donald Court for his advice, and Dr. D. S. Thomson, Dr. J. Oldfield, and Mr. J. Andrews for assistance.

GENERAL PARALYSIS OF THE INSANE

TREATED WITH PENICILLIN

REPORT ON 7 CASES

ROBERT H. F. SMITH
M.D. Belf.
SENIOR PHYSICIAN, RUNWELL HOSPITAL; LATE ASSISTANT MEDICAL OFFICER, COUNTY MENTAL HOSPITAL, LANCASTER

PROMISING results in general paralysis of the insane have been described in the United States, following intramuscular and intrathecal injections of the sodium and calcium salts of penicillin.

Stokes et al. (1944) suggested that in late syphilis, including neuro-syphilis, penicillin produces clinical and serological results which are equal, if not superior, to those obtained with arsenicals and heavy metals. General paralysis and taboparesis responded well to intramuscular penicillin.

Goldman (1945) reported that of 18 patients with dementia paralytica treated with penicillin 16 definitely improved. In this series 11 patients were each given a total of 800,000 units of penicillin intramuscularly in doses of 20,000 or 25,000 units every four hours. At the same time intrathecal injections of 10,000 units were given daily for the first two days and of 20,000 units daily for four subsequent days. A month later, intramuscular penicillin alone was given in doses of 20,000 and 25,000 units every four hours until 1,000,000 units had been administered. Of these 11 patients 3 apparently recovered, 3 were much improved, 3 improved, and 2 died. The remaining 7 patients were treated with about thirty hours' fever, induced by diathermy induction current and an insulating blanket in sessions of $2^1/_2$–3 hours at 105°F or over, three times weekly for four weeks. After the third or fourth fever treatment penicillin 20,000 or 25,000 units every four hours to a total of 1,000,000 units was given. After a month 1,000,000 units was injected in a similar manner without further fever treatment. Of these 7 patients 2 apparently recovered, 3 were much improved, and 2 were improved.

Gammon et al. (1945) published observations on the blood and cerebrospinal fluid in 89 cases of neurosyphilis treated with penicillin. The sodium salt in aqueous solution was given intramuscularly every three or four hours for eight days to a total of 1,200,000 or 2,400,000 units; a few patients received 3,000,000 or 4,000,000 units. A favourable effect on the blood and cerebrospinal-fluid reactions was noted with this dosage.

Neymann et al. (1945) treated with penicillin 5 cases of chronic dementia paralytica in which mental symptoms had been present for 1–10 years. Eight different modes of treatment were used: intramuscular, intravenous, intravenous with sodium dehydrocholate, intravenous with fever, intracisternal plus intravenous plus fever, intracisternal plus intramuscular plus phenarsone sulphoxylate, intracisternal, and intracisternal plus intramuscular. Only 1 patient improved after having intracisternal penicillin in three doses of 20,000 units and fifteen doses of 30,000 units over a period of more than three weeks. The last ten injections of 30,000 units were given daily. Of the other patients 2 died in coma from penicillin encephalopathy, 1 died as a result of exhaustion two weeks after the end of treatment, and 1 showed no improvement. Since the patients showed no improvement with intramuscular and intravenous penicillin, and the substance was not found in the cerebrospinal fluid, they conclude that "the intravenous and intramuscular injection of penicillin is ineffective because the hematoencephalic barrier cannot be breached."

ADMINISTRATION OF PENICILLIN

Dosage.—Stokes et al. (1944) treated neurosyphilis with intramuscular penicillin, using two grades of dosage: (1) 1,200,000 units or less, usually given as 25,000 units every three or four hours, day and night; and (2) 2,400,000–4,000,000 units or more, usually given as 25,000–50,000 units every two to four hours, day and night. They state that "off hand there was no striking difference recognisable between the effect of shorter time intervals or larger doses except the induction of Herxheimer reactions, which could be avoided by reduction in the dosage."

It was decided to treat the cases in my series with a total dose of 1,280,000 units of penicillin intramuscularly in doses of 20,000 units every three hours day and night, and to repeat this course at the end of a month. The first 4 patients had been given their initial course of penicillin, when a report published by Gammon et al. (1945) came to hand in which they concluded, from observations on the blood and cerebrospinal fluids of patients with neurosyphilis treated with penicillin, that "when a comparison of the results of treatment was made in two groups of patients, one receiving a low dose of 1·2 million units and the other receiving a high dose of 2·4 million units no difference was shown between them, but when the time element was taken into account—that is, when the cases were followed long enough to obtain the maximum effect—there appeared to be a slightly better response in the higher dosage group." It was decided, therefore, to increase the dose of penicillin to 50,000 units intramuscularly every four hours day and night until a total of 2,400,000 units had been given in the fresh cases and to repeat this course after a month. It was also decided to give the first 4 patients this increased dosage for their second course of treatment.

Route.—Intermittent intramuscular administration was chosen in all the cases. Only one of the patients refused to have the night injections towards the end of the second course of treatment; these were stopped, but the total amount of penicillin was given by continuing the treatment for a few days longer. None of the patients complained of any pain or irritation at the sites of injection.

Concentration in Blood and Cerebrospinal Fluid.—Studies of the penicillin content of the blood-serum after intramuscular injection were in general agreement with those reported by Fleming et al. (1944) and others. The agar-plate method of biological assay, with *Staph. aureus* as the test organism, was used. With doses of 20,000 units traces of penicillin were found in the blood at the end of three hours, and with doses of 50,000 units at the end of four hours.

No penicillin was found in the cerebrospinal fluid in my cases after 20,000 units or 50,000 units.

TOXIC EFFECTS

In this series the following toxic reactions to penicillin have been observed:

Febrile Reactions

All the patients during treatment had their temperatures recorded every four hours. In case 1 on the first day of treatment the temperature, which was normal to begin with, rose to 101°F at 2 P.M., fell to 99·5°F by 6 P.M., and became normal at night. Next day the temperature rose from normal in the morning to 99°F at 2 P.M., but at 10 P.M. returned to normal and remained so for the remainder of the treatment. In case 3 the temperature during the first day of treatment was normal, but rose to 100°F at 2 P.M. on the second day, became normal in the evening, and stayed normal for the remainder of the course. During the second course, temperatures of 100°F at 10 P.M., 102°F at 2 P.M., and 99·8°F at 6 P.M. were recorded on the 4th, 5th, and 6th days respectively, but returned to normal next day and stayed normal until treatment was completed. In cases 2, 4, 5, 6, and 7 no abnormal temperatures were noted. Cases 1 and 2 were treated at the same time, each received the same preparation and dosage of penicillin, yet one became febrile while the other remained non-febrile.

Skin Reactions

Only one patient exhibited a skin reaction. On the eighth day of treatment case 2 developed an urticarial rash on the face, neck, chest, and back. The rash on the face was red and blotchy, but on the neck, chest, and back it consisted of pale pink patches 2–3 in. in diameter, with the central part of the patches raised in weals and dead white. Fresh crops appeared at intervals during the next twenty-four hours, while the older patches slowly faded. This rash gradually disappeared when treatment ceased.

Jarisch-Herxheimer Reactions

At 12.30 A.M. on the eighth day of treatment case 2 became mentally disturbed. Previously he had been well behaved and coöperated with the staff in his treatment. He became noisy and restless and said that persons in the roof were calling him vile names and spraying poisonous gases on him. Next day he was still acutely disturbed and complained bitterly about his persecutors. He was then found to have the rash described above. Next morning he was given the last injection of penicillin at 9 o'clock; by the afternoon the hallucinations of smell had cleared, and by the following day the hallucinations of hearing had disappeared. No reactions developed during the second course of treatment.

Case 6 became mentally disturbed on the seventh day of treatment. Before and during the early part of his treatment he was quiet, but later he became abusive to the staff, accusing them of all forms of criminal intent. He paced the ward glancing furtively round and at night became noisy. Next day he was talkative and at night was so noisy that the night injections were withheld. As he was more settled the following morning, treatment was resumed, and he completed the treatment without further reaction.

BLOOD AND CEREBROSPINAL FLUID AFTER TREATMENT

Table I summarises the findings in the blood and cerebrospinal fluid before and 2–18 weeks after treatment. The findings in the 6 surviving patients 9–13 months after treatment are set out in table II; none of these has required re-treatment.

Cerebrospinal Fluid.—A decrease in cells was an early feature noted in all the cases. The cells became normal in 5 cases. A lowered protein content was also an early change observed in all the cases. This change took place simultaneously with the decrease in cellular content. The colloidal-gold reaction appears to be somewhat resistant to the treatment given. The Wassermann reaction in 5 cases remained unchanged within the observation period.

Blood.—In 5 cases the Wassermann reaction of the sera remained unchanged after two courses of treatment.

CLINICAL NOTES

Some improvement has been observed in every case.

Case 1.—A man, aged 49, with six weeks' history, was admitted on June 7, 1945, being restless, confused, auditorily hallucinated, ataxic, with tremulous limbs and spastic dysarthria, and doubly incontinent. He remained in this state until the sixth day of penicillin treatment, when his confusion and restlessness began to clear, and he regained control of the bladder and bowel. No further change was noted after the second course of treatment. A year after treatment he is demented and auditorily hallucinated, but his gait and articulation are normal. He is in hospital but does work under supervision.

Case 2.—A man, aged 44, with six months' history, was admitted on June 8, 1945, being elated, euphoric, deluded, and disoriented in time and space, with tremulous lips and tongue, slurring articulation, tremulous limbs, ataxic gait, and illegible and tremulous handwriting. On the eighth day of treatment he became mentally disturbed, and a rash appeared on his face, neck, chest, and back. After penicillin treatment ended, his mental condition improved and the rash cleared. Two weeks later the tremulousness of the lips, tongue, and limbs disappeared. He became oriented in time and space and was employed in occupational therapy rug-

TABLE I—EFFECT OF CALCIUM PENICILLIN ON THE BLOOD AND THE PARETIC FORMULA

Case no.	Before treatment					Interval (days)	After treatment

7	13	Not done	+++	50	5554331000	2

making. The second course of penicillin was given without the appearance of any toxic reaction. He was granted parole on Oct. 31, was discharged from the hospital, fit and well, on Dec. 1, and has remained well. Eleven months after treatment he is at work.

Case 3.—A man, aged 48, with six months' history, was admitted on June 1, 1945, being slovenly, untidy, elated, and fatuous. His gait was unsteady, handwriting tremulous, and articulation slurring. After the second course of treatment he became neat and tidy, and his gait and handwriting became normal. His elation disappeared, and his articulation improved. He left the hospital fit and well on Sept. 29, and has remained so ever since. A year after treatment he is at work.

Case 4.—A man, aged 51, with four weeks' history, was admitted on July 27, 1945, being dull, apathetic, and demented, with poor memory and retardation of thought. His gait was ataxic and his articulation slurring. After two courses of penicillin his gait improved, but his mental condition has remained unchanged. He left the hospital on Nov. 24. Nine months after treatment he is still demented and unable to work.

Case 5.—A man, aged 46, with twelve months' history. On admission on Sept. 8, 1945, he was elated, euphoric, and hypomanic, with spastic dysarthria, unstable emotions, and impaired memory. After treatment his mood became normal and his articulation improved, but his memory is slightly impaired. He was discharged from hospital on Feb. 2, 1946, and ten months after treatment is at work.

Case 6.—A man, aged 56, with three weeks' history, was admitted on Sept. 14, 1945, being elated, euphoric, and full of grandiose ideas about solving the housing problem. On the seventh day of treatment he became mentally disturbed, but when the course ended he became more composed. His elation and euphoria disappeared, but the grandiose delusions persisted. Three weeks later he developed lobar pneumonia, from which he died. Necropsy showed thickened meninges and ependymitis in the fourth and lateral ventricles. The brain has been prepared for histopathological study.

Case 7.—A man, aged 56, with six weeks' history, was admitted on Oct. 23, 1945, being garrulous, elated, and grandiose, with delusions of great wealth. After penicillin therapy he became less talkative, and the euphoria disappeared. His handwriting, which was tremulous before treatment, has improved, and the delusions have disappeared. He was discharged on March 30, 1946, and thirteen months after treatment he is at work.

COMMENT

It might be argued that failure to detect penicillin in the cerebrospinal fluid after moderate doses should be regarded as a contra-indication to its use in general paralysis of the insane. However, Lourie (1943) says: "While it remains true that a compound found in the cerebrospinal fluid has not necessarily traversed the tissue spaces of the brain, yet it may to some slight extent have done so. There can likewise be no unequivocal interpretation of a failure to detect the compound in the cerebrospinal fluid. While this might well mean that it had not passed the blood-brain barrier, there does remain the possibility that it may in fact have been in effective concentration in the minute perivascular spaces of the brain, but on reaching the subarachnoid space it may have become so diluted in the bulk of fluid formed at the choroid plexuses as to be no longer detectable."

The clinical and serological results in this series suggest that penicillin may have penetrated into the brain in this way.

SUMMARY

Seven patients with general paralysis of the insane have been treated with calcium penicillin intramuscularly.* Cases 1, 2, 3, and 4 had a first course of 20,000 units three-hourly day and night for a total of 1,280,000 units, followed at an interval of a month or longer by a second course of 50,000 units four-hourly day and night for a total of 2,400,000 units. Cases 5 and 7 were given two courses of 50,000 units four-hourly day and night until a total of 2,400,000 units had been given. The second course was given a month after the end of the first. Case 6 had one course of treatment of 2,400,000 units.

No penicillin was found in the spinal fluid with such dosage.

A skin reaction developed in case 2, febrile reactions in cases 1 and 3, and Jarisch-Herxheimer reactions in cases 2 and 6.

Serological results in the spinal fluid were improved with regard to cells and protein, but the colloidal-gold and Wassermann reactions were more resistant. The blood Wassermann reactions were unchanged.

Clinical results have been encouraging: 4 patients have made a social recovery, 1 has greatly improved, 1 is not improved, and 1 died.

My thanks are due to Dr. J. D. Silverston, medical superintendent of the hospital, for permission to publish this paper; Mr. A. T. Rennie, laboratory technician at the hospital, for his kind assistance; and Mr. H. Lewty, pharmacist at the hospital, and his assistants for the preparation of the aqueous penicillin solutions for injection. The Wassermann reactions of the blood and cerebrospinal fluid were kindly carried out at the Public Health Laboratory, Manchester, under the direction of Prof. H. B. Maitland, to whom my thanks are also due.

---

* Since this paper was submitted for publication, 10 other patients have been treated with penicillin alone. The results will be published later.

"... may fail to adapt successfully to the problem of advancing age.... The patient alternates between hope and despair, or becomes peevish and irritable, and begins to lose affection even for his sons and daughters. Shutting himself up in his own room, he begins to lead a solitary, introspective, selfish life. The hobbies and occupations which had interested him once cease to give satisfaction. He loses interest in external affairs, does not look at the papers, stops reading books. His life has been a failure and a waste of time. Death is approaching, and he is afraid of death, miserable, making his family miserable as well. Then the intellect may start to fail. He begins to have hallucinations and delusions, imagining mistakes and failures in his past. Thus the mind may give way before the body starts to decline, in the same way that the schizophrenic fails on the threshold of adult life.

"Most grow old with better grace.... Reacting intellectually rather than emotionally to the experience of growing old, they realise that it is better to be interested in all the seasons than to remain in perpetual love with the spring."—Dr. A. E. CLARK-KENNEDY in *Medicine*. (Edinburgh: E. & S. Livingstone, 1947, vol. i, p. 320.)

DIPHTHERIA AND STREPTOCOCCAL CARRIERS IN LONDON SCHOOL-CHILDREN

MEMBERS OF THE STAFF OF THE PUBLIC-HEALTH DEPARTMENT, LONDON COUNTY COUNCIL

THE data here presented are the results of surveys carried out in September, 1942, and February and March, 1943, to estimate the diphtheria and streptococcal carrier-rate in London school-children.

TABLE I—NUMBER OF CHILDREN EXAMINED

School medical division	Male (yr.)		Female (yr.)		Total
	Under 10	10 and over	Under 10	10 and over	
September, 1942					
North ..	117	74	108	101	400
North-west ..	105	132	94	61	392
North-east ..	85	100	91	125	401
South-east ..	73	112	74	136	395
Total ..	380	418	367	423	1588
February and March, 1943					
North-west ..	135	105	123	69	432
North ..	132	124	116	108	480
North-east ..	37	101	37	144	319
South-east ..	87	108	93	122	410
South-west ..	99	133	83	92	407
Total ..	490	571	452	535	2048

The full significance of the findings can be measured only in the light of further surveys associated with the epidemic trends of diphtheria and streptococcal infections during the periods of observation. The findings in these surveys are, however, of sufficient importance to justify publication in their present form.

Method

An attempt was made to examine 1500–2000 school-children in each survey. Since additional staff was not available, the work was divided between several doctors, and this enabled the surveys to cover all parts of London within a relatively short time, though it introduced the possibility of variation in the technique of swabbing. London is divided into five administrative divisions for school medical work, and wherever possible only one school doctor took swabs in each division. From a given date these doctors took swabs from all children seen by them in the mornings at routine medical inspection in elementary schools until the required number of swabs was obtained. The time required was usually four or five weeks. Swabs taken in the morning were delivered at the laboratory at the end of the morning session.

TABLE II—NUMBER OF CHILDREN FOUND TO BE IMMUNISED AGAINST DIPHTHERIA

Age (yr.) and sex	No. examined	Immunised	Standard deviation of percentage
September, 1942			
Under 10:			
Males	380	210 (*55·3%*)	2·6
Females ..	367	204 (*55·6%*)	2·6
Total ..	747	414 (*55·4%*)	1·8
10 and over:			
Males	418	219 (*52·4%*)	2·4
Females ..	423	220 (*52·0%*)	2·4
Total ..	841	439 (*52·2%*)	1·7
Grand total ..	1588	853 (*53·7%*)	1·3
February and March, 1943			
Under 10:			
Males	490	311 (*63·5%*)	2·2
Females ..	452	267 (*59·1%*)	2·3
Total ..	942	578 (*61·4%*)	1·6
10 and over:			
Males	571	391 (*68·5%*)	1·9
Females ..	535	341 (*63·7%*)	2·1
Total ..	1106	732 (*66·2%*)	1·4
Grand total ..	2048	1310 (*64·0%*)	1·1

For convenience of working, the bacteriological examinations were carried out in five laboratories. Swabs were plated on a tellurite-blood or serum-agar medium and on plain blood-agar. Gravis and intermediate strains of *C. diphtheriæ* were accepted as toxigenic. Mitis strains were tested for virulence.

In the first survey the doctors were asked to note the clinical condition of the nose and throat. This did not produce results that could be analysed statistically. For the second survey a "yes" or "no" was obtained concerning the following three conditions:

(1) Enlarged or unhealthy tonsils; history of sore throat.
(2) Adenoids or nasal catarrh.
(3) History of tonsillectomy.

This questionnaire gave results of some value, but the accurate assessment of abnormalities of the nose and throat is extremely difficult and depends to a great extent on personal opinions.

Results

The results are summarised in tables I-V.

It was impossible to include the south-western division in the first survey. The 1943 survey, however, covered the whole of the county area. It is seen that the method used for selection of children achieved a fair distribution between the sexes and age-groups.

TABLE III—STREPTOCOCCAL CARRIERS

Age (yr.) and sex	No. examined	Hæmolytic streptococcus found			
		Nose	Throat	Nose and throat	All sites
September, 1942					
Under 10:					
Males ..	275	7 (*2·5%*)	27 (*9·8%*)	7 (*2·5%*)	41 (*14·9%*)
Females	273	9 (*3·3%*)	27 (*9·9%*)	7 (*2·6%*)	43 (*15·8%*)
Total ..	548	16 (*2·9%*)	54 (*9·9%*)	14 (*2·6%*)	84 (*15·3%*)
10 and over:					
Males ..	286	9 (*3·1%*)	36 (*12·6%*)	9 (*3·1%*)	54 (*18·9%*)
Females	362	10 (*2·8%*)	43 (*11·9%*)	3 (*0·8%*)	56 (*15·5%*)
Total ..	648	19 (*2·9%*)	79 (*12·2%*)	12 (*1·9%*)	110 (*17·0%*)
Grand total	1196	35 (*2·9%*)	133 (*11·1%*)	26 (*2·2%*)	194 (*16·2%*)
February and March, 1943					
Under 10:					
Males ..	490	11 (*2·2%*)	60 (*12·2%*)	11 (*2·2%*)	82 (*16·7%*)
Females	452	10 (*2·2%*)	45 (*10·0%*)	6 (*1·3%*)	61 (*13·5%*)
Total ..	942	21 (*2·2%*)	105 (*11·1%*)	17 (*1·8%*)	143 (*15·2%*)
10 and over:					
Males ..	571	9 (*1·6%*)	50 (*8·8%*)	3 (*0·5%*)	62 (*10·9%*)
Females	535	6 (*1·1%*)	59 (*11·0%*)	3 (*0·6%*)	68 (*12·7%*)
Total ..	1106	15 (*1·4%*)	109 (*9·9%*)	6 (*0·5%*)	130 (*11·7%*)
Grand total	2048	36 (*1·8%*)	214 (*10·4%*)	23 (*1·1%*)	273 (*13·3%*)

During the period in which the surveys were made an immunisation drive was taking place in the schools, and the improved figures in 1943 show the progress of the campaign. Evidence from other sources suggests that the percentages in table II were representative of the state of immunisation of London school-children at the times of the surveys. This table demonstrates the value of the small-scale sample survey as a means of providing a close estimate of such measurable characteristics in the population.

The swabs examined for diphtheria gave the following results:

September, 1942:

No. of children examined	1588
Positive, virulent	6 (*0·38%*)
Positive, non-virulent	8 (*0·50%*)
Total positive ..	14 (*0·88%*)

(Of the 14 positives, 7 had been immunised and 7 had not.)

February and March, 1943:

No. of children examined	2048
Positive, virulent	4 (0·19%)
Positive, non-virulent	2 (0·10%)
Total positive ..	6 (0·29%)

(Of the 6 positives, 5 had been immunised and 1 had not.)

The diphtheria carrier-rates were unexpectedly low and certainly much lower than estimates made at various times in pre-war years. Some past estimates have been based on the results of swabbing selected groups of children (including diphtheria contacts) and for this reason were too high. Forbes,[1] referring to the systematic swabbing of children in *affected* class-rooms on the chance of finding the elusive carrier, states: "Since 1903 records of such investigations deal with over 74,000 more or less selected children, among whom the carrier-rates in the following 25 years have shown considerable variation, the highest being 19·3% in 1916 and the lowest 3·3% in 1919, with averages for various periods of 6·3% from 1903 to 1909, 12·2% from 1910 to 1919, and subsequently 6–7%. The proportion of carriers to the total population in England has been estimated[2] at 4·6%." Tellurite media will give a higher incidence than Loeffler. Moreover, for various reasons, the incidence of diphtheria in London was considerably lower during the war years than in pre-war years.

TABLE IV—GROUPS OF HÆMOLYTIC STREPTOCOCCI FOUND

Lancefield group	1942	1943
A	159 (79·6%)	211 (77·1%)
B	—	—
C	25 (12·5%)	25 (9·2%)
G	1 (0·5%)	1 (0·4%)
Not grouped ..	15 (7·7%)	35 (12·7%)

It is interesting to view the carrier-rate figures in the light of the immunisation campaign. The danger that immunisation will lead to an increase in the carrier-rate may not be so great as was thought. It can be stated as a result of these surveys that immunisation of two-thirds of the child population between five and fourteen years of age is compatible with a diphtheria carrier-rate of considerably less than 1%.

Table III shows that not all the children in the first survey were examined for hæmolytic streptococci.

TABLE V—PRESENCE OF HÆMOLYTIC STREPTOCOCCI (H.S.) AND ABNORMALITIES OF NOSE AND THROAT

	Hæmolytic streptococcus				H.S. not found	Total	% with H.S.
	Nose	Throat	Nose and throat	Total			
Adenoids or nasal catarrh	7	25	5	37	191	228	16·2
History of sore throat or enlarged or unhealthy tonsils	7	45	3	55	257	312	17·6
History of tonsillectomy ..	5	12	2	19	226	245	7·8
No abnormality ..	17	131	13	161	931	1092	14·7

The peak of an epidemic of scarlet fever came between the times of the two surveys, and the relation between the attack-rate of scarlet fever and the streptococcal carrier-rate may be expressed as follows:

	Children aged 5–14 yr. Attack-rate of scarlet fever per 1000 per week	*Incidence of hæmolytic streptococcus %*
During 1942 survey ..	0·22	16·2
During 1943 survey .	0·26	13·3

Table IV shows the results of grouping the streptococci found. The highest incidence of hæmolytic streptococci (table V) was found in the children with unhealthy tonsils, but the figures for these children are not greatly in excess of those in the children with no clinical abnormality of the nose and throat. The incidence of hæmolytic streptococci in children with a history of tonsillectomy was, however, significantly lower than in all other groups.

The results shown are based on swabs taken on only one occasion from each child. There is nothing to show which of the positives were persistent carriers, and which were purely temporary carriers. The results therefore shed no light on the relation between unhealthy conditions of the nose and throat and the persistent carrier state.

The investigation was planned and supervised by Dr. Ian Taylor. The swabbing and examination of children was undertaken by medical officers of the school medical service, and the bacteriological examinations by the staff of the group laboratories. The statistical work was performed by Mr. B. Benjamin. The surveys were carried out with the permission and encouragement of Sir Allen Daley.

TREATMENT OF THYROTOXICOSIS WITH PROPYL THIOURACIL

ANDREW WILSON
M.D., Ph.D. Glasg.
LECTURER IN PHARMACOLOGY AND THERAPEUTICS, UNIVERSITY OF SHEFFIELD

JOHN GOODWIN
M.D. Lond., M.R.C.P.
RESEARCH FELLOW AND TUTOR IN THERAPEUTICS IN THE UNIVERSITY

THAT thyrotoxicosis can be effectively controlled with thiouracil or methyl thiouracil has been established by the many reports from Europe and the U.S.A. In a quest for more potent and less toxic compounds Astwood et al. (1945) tested some 300 substances for anti-thyroid activity and showed that in the rat propyl thiouracil exerts a longer effect and is ten times more potent than thiouracil. This has been confirmed for the rat by Bavin and Goodchild (1946) and for the chick by Vanderlaan (1945). In a clinical trial thyrotoxicosis was rapidly controlled with propyl thiouracil without any untoward reactions (Astwood and Vanderlaan 1945). Further, some patients who had previously reacted adversely to other anti-thyroid substances did not do so to propyl thiouracil.

We summarise here our experience with propyl thiouracil in treating 16 patients with thyrotoxicosis. All of them presented the typical signs and symptoms of hyperthyroidism, which had lasted from two months to nine years. In no instance had iodine been given for at least four months before treatment with propyl thiouracil. The therapeutic value of the drug was assessed by the criteria already described (Wilson 1946).

TREATMENT

From the results of the animal experiments already cited it was estimated that the initial dose of propyl thiouracil necessary for control of thyrotoxicosis would be about 80 mg. daily. Preliminary observations on two patients given 75 mg. daily indicated that full response was not effected for at least three weeks. It was therefore decided to use a daily dose of 150 mg. given as two 25-mg. tablets three times daily till full control of signs and symptoms was evident. Thereafter the dose was reduced to 75 mg. daily and later to 50 mg. or 25 mg. daily. White-cell counts were done on an average three times a week till the maintenance dose was reached. The patients were then discharged to the outpatient department for observation at intervals of three or four weeks.

RESULTS

The order of the disappearance of signs and symptoms after the beginning of treatment is indicated in table I.

TABLE I—RELIEF OF SIGNS AND SYMPTOMS IN DAYS AFTER START OF TREATMENT

Signs and symptoms	Thiouracil 1000–1800 mg. daily	Methyl thiouracil 600 mg. daily	Propyl thiouracil 150 mg. daily
Subjective improvement; restlessness relieved	4–8	3–5	3–9
Sweating and skin flush controlled	6–14	4–7	4–13
Tremor diminished ..	10–20	5–12	5–18
Gain in body-weight	10–25	7–15	6–18
Tachycardia controlled	15–30	9–17	4–30
Serum-cholesterol increased, or basal metabolic rate reduced	10–20	6–12	10–20

The results obtained with propyl thiouracil are compared with the observations previously made on patients treated with thiouracil and with methyl thiouracil. The control of thyrotoxicosis is more rapid with propyl thiouracil than with thiouracil. Apart from the smaller dose of propyl thiouracil, the lag between the beginning of treatment and response is not less than was observed in patients treated with methyl thiouracil. Thus, though propyl thiouracil is about four times as potent as methyl thiouracil, it does not control thyrotoxicosis more rapidly.

Primary and Secondary Goitre

It is often said that patients with primary thyrotoxicosis respond to treatment with the anti-thyroid substances more effectively than do patients with secondary goitre. This has not been our experience in a large series of patients treated with thiouracil or with methyl thiouracil. Particular attention was paid to this aspect during the trial with propyl thiouracil, and the observations made on 5 cases of primary and 6 cases of secondary thyrotoxicosis are set out in table II. The results indicate that the response to treatment is more rapid in patients with secondary goitre. This may partly be explained by the fact that the precipitating factor of anxiety is initially more difficult to control and the restoration of the normal pulse-rate is usually more delayed.

Toxic Effects

Though there were periodic fluctuations in the white-cell counts, particularly during the first two weeks' treatment, in no instance did the total white-cell count fall to less than 4500 per c.mm. Granulopenia was not observed.

One patient developed an irritating rash on the hands, thighs, and buttocks seven weeks after beginning treatment. She did not report to hospital at once but continued taking her tablets for three weeks.

On examination there was a papular lichenoid eruption on the thighs, and an acute cheiropompholyx on the hands, which bore the signs of an acute toxic dermatitis. There was no splenomegaly, icterus, or lymphadenopathy. No fetor; no sore throat. White cells 8800 per c.mm. (polymorphs 51%, eosinophils 6%). Previous eosinophil counts had never been more than 1%. The thyrotoxicosis was still well controlled, and there was no enlargement of the adenoma.

When the rash developed she was taking 50 mg. daily and had had a total dosage of 3·8 g.

On her readmission to hospital propyl thiouracil was withdrawn, and after local treatment with diatomite lotion the skin lesion gradually disappeared without further incident.

DISCUSSION

There is no doubt that propyl thiouracil is effective in controlling thyrotoxicosis. The potency of propyl thiouracil is about four times that of methyl thiouracil, and, on the whole, the lag between the beginning of treatment and response is about the same with both drugs. Astwood and Vanderlaan (1945), who used smaller doses, concluded that on a weight basis propyl thiouracil was about five times as potent as thiouracil.

The therapeutic efficacy of propyl thiouracil is further reflected in its ability to restore to normal sinus rhythm 4 of 6 patients with auricular fibrillation. These results are comparable with the effects already described for thiouracil (Wilson 1946). Evidence is increasing that the anti-thyroid substances offer a reasonable chance of restoring normal rhythm in such patients; and, in view of the relatively poor results with digitalis in cases unsuitable for operation, the thiouracil derivatives merit further trial.

In the present trial, which included 2 patients with retrosternal goitre, no thyroid hyperplasia has been seen as a result of treatment. Due appreciation of the mechanism of thyroid hyperplasia should be reflected in the avoidance of overdosage with the thiouracil derivatives.

The range of maintenance dosage so far used is 25–75 mg. daily. It is possible that continuous treatment for a longer period than has been used in these patients will lead to the use of a smaller daily dose. At present this range is about the same as that found to be effective by Astwood and Vanderlaan (1945).

Toxic effects have been observed in one patient treated with propyl thiouracil, but the number of cases is smaller and has been observed for a shorter period than those treated with methyl thiouracil. There is thus no outstanding point of difference between these two anti-thyroid substances; and, if consideration is given to the fact that propyl thiouracil is more difficult to manufacture (Bavin 1947), there is at present no indication that propyl thiouracil should replace methyl thiouracil in the treatment of thyrotoxicosis.

TABLE II—COMPARISON OF RELIEF OF SIGNS AND SYMPTOMS OF PRIMARY AND SECONDARY THYROTOXICOSIS IN DAYS AFTER TREATMENT WITH PROPYL THIOURACIL 150 MG. DAILY

Signs and symptoms	Primary (5 cases)		Secondary (6 cases)	
	Average	Range	Average	Range
Subjective improvement; restlessness relieved	5	4–9	4	3–5
Skin flush controlled	8	4–13	5	4–6
Sweating controlled ..	10	6–13	6	4–9
Tremor diminished ..	10	7–17	9	5–18
Gain in body-weight..	8	6–10	13	7–18
Tachycardia controlled	13	4–30	11	4–23

SUMMARY

The results of treating 16 cases of thyrotoxicosis with propyl thiouracil for periods of up to nine months have shown that this drug is about four times as potent as methyl thiouracil.

The response to propyl thiouracil is not more rapid than that to methyl thiouracil, and the maintenance dose is slightly greater for propyl thiouracil.

Thyroid hyperplasia has not been observed with the doses used.

Toxic effects on the skin were seen in one patient after seven weeks' treatment with propyl thiouracil.

There is no evidence that patients with secondary thyrotoxicosis respond less effectively than do those with primary thyrotoxicosis.

There is no evidence that propyl thiouracil has any outstanding advantage over methyl thiouracil in the treatment of thyrotoxicosis.

We wish to thank Prof. E. J. Wayne for the opportunities of studying the cases under his care; Prof. A. E. Barnes, Dr. A. G. Yates, Dr H. P. Brody, and Dr. A. W. Leishman for their valuable coöperation; and Messrs. Genatosan Ltd. for supplies of propyl thiouracil. Part of the expenses of this research were defrayed by a grant from the Medical Research Council to one of us (A. W.).

TREATMENT OF FISTULA IN ANO

J. P. Lockhart-Mummery
F.R.C.S., F.A.C.S.
CONSULTING SURGEON, ST. MARK'S HOSPITAL, LONDON

When reviewing the cases which have come under my care during some forty years of surgical practice, I was struck by the fact that, of all the different conditions with which I have been called on to deal, fistula in ano has always ranked as one of the most difficult and tedious. This is largely because there is no certain means of curing it, and success can be achieved only by patience and close attention to detail. This mainly applies to bad cases of fistula, of which no doubt I have had a disproportionate number.

The treatment of fistula in ano has never received the attention it seems to deserve in surgical textbooks and in the teaching of the medical schools. In the early days of surgery it was considered incurable, and even today, judging from the many cases operated on several times without success, it seems that the treatment is still far from satisfactory and the principles of successful treatment not well understood.

The first known treatise on a special surgical subject was one dealing with fistula in ano—a small book, or rather parchment, written by John of Arderne in A.D. 1349 at the time of the Black Prince. John of Arderne practised at Newark. He was a bold and able surgeon with a considerable reputation. He describes his method of dealing with fistula in great detail and recounts the steps of the operation by which he cured Sir Adam Everingham of a grievous fistula. His fee was £70, and the purchasing power of money was then much greater than it is today. Arderne's operation was sound in principle, even judged by modern standards. He did not use the actual cautery or caustic dressings as did many of his contemporaries.

In the early part of last century the treatment of fistula was so unsatisfactory in the general hospitals of London that David Salmon was induced to found St. Mark's Hospital (at that time in Aldersgate Street) for the special purpose of relieving poor persons afflicted with the condition.

PRINCIPLES OF OPERATION

A bad case of fistula in ano presents the surgeon with one of his most tricky problems. There is no set operation, so each case has to be studied and a suitable procedure planned. The personal attention of the surgeon who performs the operation should be given to the after-treatment of the case. I have never undertaken an operation for fistula unless the circumstances allowed of my being able to supervise personally the postoperative treatment.

There are some general principles which should be carefully observed. First, it is very unwise to operate for the cure of a fistula when any acute sepsis or an undrained abscess is present. The proper procedure is to lay open and thoroughly drain any abscesses or septic foci and postpone the real operation until all acute sepsis has subsided. This means delay, and it should be explained to the patient that the cure of a fistula is a slow process and cannot be hurried.

Unless the fistula is a simple one, the main track communicating with the rectum, which, however complicated the whole lesion may be, is almost invariably single, should be left to be divided at a subsequent operation, attention being confined to freely opening up all the secondary tracks to provide free drainage throughout the healing process. All tracks should be made to communicate with each other to form one large open wound. It is often difficult because of their complexity to trace the fistulous tracks with a probe, and a better method is to feel for them in the thickness of the tissues with one finger in the rectum.

A very careful search should be made to discover if there is a deep cross track behind the anal canal. Such a track is often present, and if it remains undetected and undrained is a common cause of non-healing of the wound.

There should be no hesitation in cutting away unhealthy tissue or overhanging skin edges. Deformity of the parts is much more likely to result from not cutting away enough skin than from cutting away too much.

If the tracks are freely opened and the skin edges and all unhealthy tissue cut away to provide really free drainage, there is no necessity to pack the wounds with wool or gauze at the end of the operation. They are best left wide open to drain into a large flat dressing. Hæmorrhage must be stopped with ligatures or by the application of hot swabs. This procedure does away with the subsequent necessity of pulling out a lot of adherent packing, and besides saving the patient much pain and discomfort allows the granulating surfaces to form without disturbance. After the wound has granulated, light packing with wool may be used. It should be placed in position dry and then damped with castor oil. The dressing should be done twice daily after all packing has been removed and the patient has had a soak in a hot bath. There is no point in using antiseptics at this stage; they delay healing by damaging the granulations. The use of sulphanilamide powder at the time of operation may, however, check sepsis and hasten the formation of healthy granulations.

At the end of a fortnight or three weeks the patient should be again anæsthetised and the main track communicating with the rectum freely divided to leave a free opening between the wound and the interior of the anal canal.

The surgeon should himself do the dressing at least once a week to satisfy himself that the deep parts of the wound are healing correctly and that no pockets have formed. Any pockets or fresh tracks which form during healing should be at once opened and drained.

In the vast majority of fistulæ the deep track communicating with the rectum is single and situated on the posterior wall of the anal canal. I once saw a patient at St. Mark's Hospital with eighteen external fistulous openings spread about all over both buttocks, but there was only one track communicating with the bowel posteriorly. Very occasionally the deep track is situated to one side of the bowel and passes deep to the external sphincter. In such a case the muscle must not be divided at the first operation, or the ends will be drawn apart, and serious and probably permanent incontinence will result. The external tracks should be divided and the muscle left bridging the wound. After two or three weeks the muscle ends will be firmly held in the scar tissue and the muscle may be divided without fear of the ends retracting.

Except for getting up daily for a bath, &c., the patient should stay in bed till all the wounds are healed. If he is allowed to get up too soon, healing will probably be greatly delayed.

INCURABLE FISTULÆ

Not all fistulæ are curable, though the great majority are. In a long experience I have met with only two really incurable cases. In both there was a deep track some 6 in. long passing up to one side of the rectum and communicating with an abscess cavity inside the prostatic capsule. There was in both cases reason to believe that the original lesion was a prostatic abscess. Without removing the greater part of the prostatic gland an operation to cure the condition was not possible, and in neither case was it attempted. The subsidiary tracks were dealt with in the usual way and the prostatic track opened up as much as possible to allow a large-bore drainage tube to be introduced. This tube was arranged so as to be self-retaining and was kept in place for several years, *being changed twice daily*. The ultimate result in both cases was that the prostatic track became completely lined with epithelium and formed a permanent drain which required no attention. Though this may not seem an ideal method of dealing with such a fistula it resulted in a patient who had previously suffered from constant attacks of acute sepsis and abscess remaining quite comfortable and free from such attacks.

NEOANTERGAN IN THE TREATMENT OF URTICARIA

REPORT ON 14 CASES

R. B. HUNTER
M.B.E., M.R.C.P.E.
LECTURER IN THERAPEUTICS, UNIVERSITY OF EDINBURGH
From the Clinical Laboratory, The Royal Infirmary, Edinburgh

THE work of Best, Dale, Dudley, and Thorpe (1927) established beyond reasonable doubt that normal living tissues contain histamine. Since similar symptoms were produced by a histamine injection and by an anaphylactic reaction Dale (1929) argued that histamine was probably the cause of anaphylaxis, the source of the histamine being the tissues themselves. Lewis's (1927) studies of the blood-vessels of the human skin and their responses led him to conclude that as the result of irritation a histamine-like substance was released from living cells. Since then repeated efforts have been made to discover histamine antagonists in the twofold hope that they would counteract the effects of anaphylaxis and allergy and increase our knowledge of these states.

The early anti-histamine compounds (Fourneau and Bovet 1933, Staub and Bovet 1937, Staub 1939) were all too toxic for clinical use, but in 1942 Halpern described results with a new series of compounds, the most active of which were labelled '2325 R.P.' and '2339 R.P.' The latter was named 'Antergan' and found to be much more specific against histamine than any previously discovered compound. Halpern found that very small amounts inhibited the contraction of guineapig gut induced by histamine, and he postulated that the drug does not prevent the release of histamine or influence its destruction, but modifies the tissues so that histamine is incapable of producing its customary effects.

Antergan was used by Gaté et al. (1942) with good results in urticaria, eczema, and asthma, but mild toxic effects were noted in some cases, mainly nausea, headache, vertigo, and rarely vomiting.

In 1944 Bovet reported experimental findings with a pyridine derivative of antergan ('2786 R.P.'), called by the manufacturers 'Neoantergan.' The drug used in the study reported here is the malleate of neoantergan—'Anthisan' (M. & B.).

Dews and Graham (1946) confirmed Bovet's main findings and noted several other actions of neoantergan. It is a local anæsthetic three times as potent as procaine. It has a quinidine-like action on the auricle twice as strong as that of quinidine, and it abolishes the stimulant action of histamine on cardiac tissue, the dilator action of the drug on coronary vessels, and its constrictor effect on the vessels of the rabbit's ear. Neoantergan is also a mild analgesic and is a feeble antagonist to acetylcholine on the rabbit's intestine.

Pellerat (1946), reviewing the clinical use of anti-histamine substances, states that benefit may be evident on the first, second, or third day after the beginning of treatment. If there is no improvement after three days the drug should be stopped. He found that children tolerated anti-histamine drugs very well, and gave infants 0·15 g. per day, children under five years 0·15–0·3 g., and children over five years, 0·3–0·6 g. He gave adults 0·6 to 1 g. in the twenty-four hours. Of the urticarias in his series 80–90% were "cured," and with neoantergan a well-marked improvement in 45% of cases of asthma was claimed. Cases of hay-fever and rhinorrhœa were strikingly benefited. The main side-effects noted were anorexia or nausea, which could be minimised by giving the drug with sugar and water or with sodium bicarbonate. Other side-effects were headache, dizziness, lassitude, sleepiness, palpitation, and slight anxiety; rarely vomiting or drug fever. Decour (1945) found that neoantergan had no effect on the hydrochloric acid content of the gastric juice, or on the gastric response to histamine. His patients were given neoantergan in full dosage for several months without untoward results

We have used anthisan (neoantergan malleate) in the treatment of allergic conditions since November, 1946. Only the effects in selected cases of urticaria and angioneurotic œdema will be discussed here; its use in the treatment of asthma and other presumed allergic states will be published later.

CASE-RECORDS

Case 1.—A married woman, aged 47, developed urticaria for no obvious reason in December, 1946. From then until her admission to hospital in March, 1947, she was never free from urticarial lesions. The condition was very much worse at night, and whereas at first it only affected her limbs and trunk it later involved her face, eyes, ears, and tongue *There was no family history of allergy.* In 1945 a subtotal thyroidectomy had been performed for thyrotoxicosis, with good result.

Electrocardiographic examinations carried out before antihistamine treatment was begun and again while the patient was having 0·5 g. of anthisan daily gave no evidence of a quinidine-like effect. The patient had a histamine fast achlorhydria. The anthisan had no effect on the blood-pressure or on the differential white-cell count. There was no eosinophilia at any time.

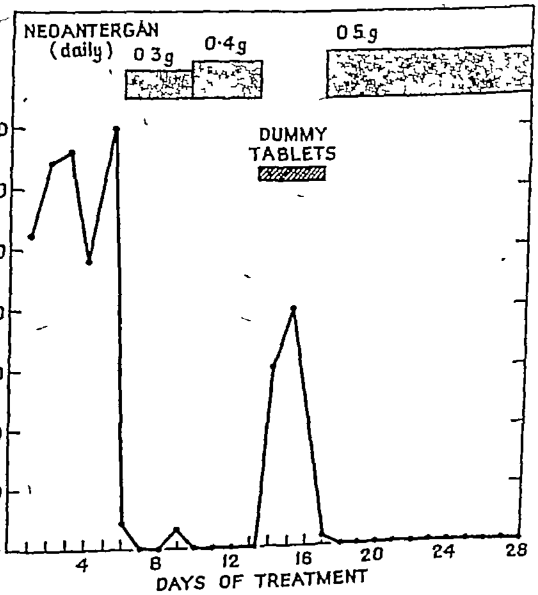

Fig. 1—Case 1. Urticaria treated with anthisan: note recurrence when dummy tablets were substituted.

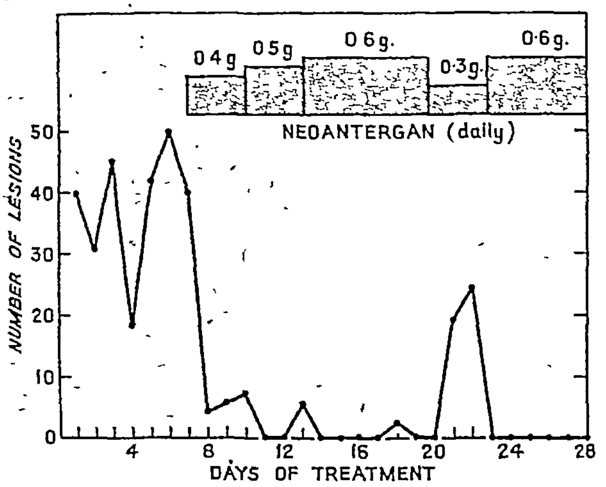

Fig. 2—Case 2. Urticaria treated with anthisan. A daily dosage of 0·6 g. was required for complete relief.

The patient continued taking 0·5 g. of anthisan daily for a month with no increased tolerance to the drug. The effect on the lesions is shown in fig. 1. When she was put on dummy tablets the lesions seemed to be more severe than they had been before treatment. During the second month of treatment she had only 4 small urticarial patches which came out at 8 A.M. on the days when she was late in taking her morning dose.

She was sleepy on the first day of anthisan treatment, but otherwise there were no side-effects.

Case 2.—A married woman, aged 49, had an attack of urticaria in 1917 and again in 1921, both seemingly precipitated by tinned milk. Thereafter by avoiding tinned milk she kept free from urticaria until April, 1946, when she had a severe attack which lasted for ten days. On this occasion there was no possible association with milk, and thorough investigation revealed no cause for the attack. Her general health had been good, though she had gone through a period of nervous strain because of the sudden serious illness of her husband. Further urticarial attacks occurred in June, 1946, and from that time until her admission to hospital on March 4, 1947, she was never free from lesions for more than an hour day or night. During these months she had been given autohæmotherapy, bowel wash-outs, and ephedrine without result. An attempt to desensitise her with a histamine azoprotein ('Lertigon') was made without benefit. After this, 'Benadryl,' in a dosage of 50 mg. three times a day for six weeks, produced no improvement.

During treatment with anthisan no abnormality of white cells was noted, and an electrocardiogram done before and during anti-histamine treatment showed no quinidine-like effect. The effect on the lesions is shown in fig. 2. The lesions which appeared while the patient was taking anthisan were not itchy, and were retrogressive, fading within an hour or two. The patient's final dosage was 0·6 g. daily. When seen a month later she had had small retrogressive urticarial patches on two occasions only.

The patient had some transient nausea for two days after leaving hospital. She had one attack of breathlessness during treatment associated with some bronchial spasm which lasted for two hours. No other side-effects were noted apart from a slight lassitude.

Case 3.—A man, aged 52, developed angioneurotic œdema in 1938. Before that he had suffered from severe hay-fever. The attacks of angioneurotic œdema became more frequent and severe, until by 1945 lesions were appearing every two or three days in all parts of the body including the tongue and eyes. Sometimes the patient's whole arm would be swollen right down to the finger-tips, and he found that pressure on the skin by sock-suspenders or tight clothing would bring out a lesion in that area; excitement and nervous strain had the same result. Between 1945 and 1947 he had various forms of treatment. Ephedrine and adrenaline modified the condition, but he was never entirely free from symptoms and severe lesions would appear at intervals of three days to three weeks. A course of autohæmotherapy and bowel wash-outs produced little improvement but there was some definite improvement with lertigon. After 11 injections, however, he began to have so sharp local reactions to lertigon that this treatment had to be stopped.

Anthisan was strikingly successful in this case (fig. 3). When the patient had been entirely free from urticaria for a month as the result of treatment with the drug as an outpatient he was admitted to hospital and treatment was stopped. There was an immediate recurrence of angioneurotic œdema within 17 hours. Dermatographism was pronounced when he was taking dummy tablets. When anthisan was resumed he felt slightly sleepy and his mouth was dry, but there were no other side-effects. The dosage required to keep this patient completely free varies from 0·6 g. to 0·8 g. daily.

The other 5 cases of chronic urticaria treated with anthisan were all improved. Three were completely controlled with 0·6 g. anthisan a day. These patients received 0·1 g. at 8 A.M., 0·2 g. at 2 P.M., 0·1 g. at 5 P.M., and 0·2 g. at 10.30 P.M. It was found that complete control could be achieved with the minimum amount of drug if the dosage was spaced out in this way. These patients manifested the same mild side-effects which have already been mentioned. In addition one of them had a single asthmatic attack during the second month of treatment; she had never previously suffered from asthma. In the fourth case the lesions were modified in number and size with 0·3 g. a day, but the patient had so much dizziness and nausea that the drug could not be given in larger dosage. The fifth case was partially controlled with 0·8 g. anthisan in the day.

Six cases of acute urticaria were treated with definite and even dramatic results. In 2 of these benadryl in full dosage had previously produced no benefit. Five of them were cases of penicillin urticaria and in 2 of these treatment was successful even though the penicillin was continued. They required between 0·6 and 0·8 g. anthisan a day. Skin irritation disappeared within an hour and the urticaria had practically gone within three hours. In 3 of the cases the anthisan was withdrawn at the end of twenty-four hours with a return of skin irritation and urticaria, but these disappeared quickly again when anthisan was administered once more. In all these cases the treatment was stopped at the end of seven days without any recurrence of urticaria.

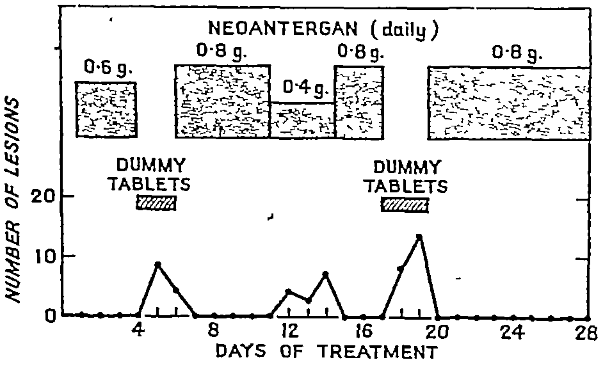

Fig. 3—Case 3. Angioneurotic œdema treated with anthisan. Note recurrence on substituting dummy tablets or reducing dosage below 0·8 g. daily.

In 3 of the acute cases the only side-effect noted was sleepiness. Two others had in addition dryness of the mouth and dizziness. One had a severe reaction with collapse, hypotension, diarrhœa, and intense nausea within an hour of 0·05 g. of anthisan being given subcutaneously; a single dose of 0·1 g. by mouth later produced a similar, though less severe, effect. This patient had fleeting joint pains while the drug was being given.

SUMMARY

Eight cases of chronic urticaria and angioneurotic œdema were treated with the anti-histamine drug,

anthisan (neoantergan malleate). The dosage required was between 0·3 and 0·8 g. a day, given in divided doses. Most of these cases were well controlled and had only mild side-effects. Once the required dosage was established increased tolerance to the drug was not observed in the first three months of treatment. Removal of the drug or reduction of the dosage was followed within ten hours to four days by a recurrence of chronic urticaria.

Six cases of acute urticaria were treated, 5 of them the result of sensitisation to penicillin, and in 2 of these the urticaria was controlled even though penicillin treatment was continued. If this effect is confirmed it will allow penicillin therapy to be continued even in patients who manifest severe urticarial reactions.

The commonest side-effects noted were sleepiness, mild headache, nausea, and dizziness. In the main they were not severe. Two patients had a single asthmatic attack during treatment. One severe toxic reaction to parenteral therapy was observed, and it is suggested that in the present state of our knowledge the drug should be administered by mouth only. It is proposed that the initial dosage should be 0·1 g. three times a day and that this should be increased as required to a maximum of 1 g. a day.

Grateful acknowledgment is made to Prof. D. M. Dunlop for his advice and criticism, and also permission to publish his case-records. We are indebted to Messrs. May and Baker Ltd. for supplies of tablets of anthisan.

SHRAPNEL SHOT THROUGH THE PLACENTA

BERNHARD ZONDEK
M.D. Berlin

From the Gynæcological-Obstetrical Department of the Rothschild Hadassah University Hospital, Jerusalem

DURING the Palestine disturbances in August, 1939, a woman, aged 24, a primipara nearing term, sustained an injury from the explosion of a nearby bomb. She felt a sharp pain in the abdomen, walked on a little way, and then collapsed. In this condition she was brought to the hospital.

On the right hypogastrium, below the umbilicus, four wounds were visible, the largest of them about 2 cm. in diameter. The innocuous external appearance of the injuries contrasted with the serious general condition. The patient was very anæmic and covered with cold sweat; the pulse was rapid and feeble. All the symptoms pointed to an internal hæmorrhage. The fœtal heart was not distinctly heard, and it was very doubtful whether the fœtus was living.

The patient was given an intravenous saline drip infusion and placed under ether anæsthesia. The abdomen was opened through a hypogastric longitudinal incision. The bomb shrapnel was found to have pierced the rectus fascia and muscle, leaving a large hole through which torn muscle protruded. There was considerable hæmorrhage.

When the peritoneum was opened, two perforations, each about 1 cm. in diameter, were found in the uterus. Blood and amniotic fluid dripped through the perforations. The abdominal cavity contained about 200 c.cm. of blood and amniotic fluid. The uterus was opened through a longitudinal incision. Its muscles had been much torn, with strips of muscle hanging loosely in the uterine cavity.

A male child was then extracted; the child was born in pallid asphyxia, which was relieved after treatment lasting 45 min. In other respects he had escaped unhurt.

The placenta was readily separable; it had been shot through near the edge. One of its blood-vessels had been perforated, from which extensive bleeding had taken place into the amniotic cavity.

After complete excision of all the torn tissues, the uterus was sutured in three layers, as in cæsarean section. The bladder had sustained no injury, and it was possible to cover the sutures with bladder peritoneum. No injury to intestines having been found, the peritoneum was closed. The torn soft tissues of the abdominal wall were excised, the skin perforations were sutured, and a drain was inserted.

The postoperative course was undisturbed except for an infection of the abdominal wall. The peritoneum gave no cause for concern. Four weeks later the patient was discharged.

Careful radiography had not revealed the shrapnel which must have entered the uterine cavity; it had doubtless been expelled thence through the vagina during the operation.

Had the patient not been pregnant, the shrapnel would undoubtedly have torn the intestines; but these were shielded by the uterus and the amniotic fluid. The fœtus therefore saved its mother.

We have kept the child under observation up to now; he has developed well physically and mentally.

Five years later, early in 1944, the patient consulted me for a missed menstruation. The Aschheim-Zondek hormonal pregnancy test was positive. The patient was aware that her pregnancy, in view of the severe uterine tear which she had sustained, entailed some danger, but she accepted the risk, as she very much desired a second child. She came to me for examination once a month. The pregnancy ran a normal course. At term the question arose whether a cæsarean section should be performed to avoid uterine rupture from the labour pains. In view of my experience in conservative myomectomy and of the favourable outcome of conservative management of delivery in cases so operated on,[1] I decided not to perform a cæsarean section. Labour ran a normal course and lasted only four hours. A healthy boy was born. The placenta was expelled spontaneously without difficulty.

PALUDRINE IN RELAPSING BENIGN TERTIAN MALARIA

FURTHER TRIALS

R. D. C. JOHNSTONE
M.D. Lond., M.R.C.P.
LATE MAJOR R.A.M.C.

FOLLOWING the trials with 'Paludrine' already reported (Johnstone 1946a), a further series of cases of relapsing benign tertian malaria were treated at Colchester Military Hospital with paludrine and quinine combined. This treatment was thought to have distinct possibilities, in view of the similarity in action of paludrine and pamaquin. As before, a control series of cases treated with the standard quinine-pamaquin course were included in the investigations. Unfortunately the number of admissions to the malaria ward fell so considerably as the investigation progressed that it was finally decided to abandon the trials before an adequate number of cases had been treated. The results, however, seem worth recording.

Exactly similar precautions, admission to hospital, and follow-up were used as in the previous investigations.

In all, 61 cases were treated on the following courses, each course being used alternately:

(1) Quinine gr. 10 and pamaquin 0·01 g. t.d.s. for 10 days.
(2) Quinine gr. 10 and paludrine 0·25 g. t.d.s. for 10 days.

---

[1] Zondek, B. *Harefuah*, 1936, **11**, 1; *Surg. Gynec. Obstet.* 1939, **69**, 214.

The final follow-up in these cases includes 29 cases of each series, two patients having failed to report in spite of repeated requests, and one patient having been accidentally killed before the end of the six-month period. The table shows the results obtained in the 58 cases successfully followed for six months.

RESULTS OF TREATMENT

Course	No. of cases	No relapse	Proved relapse	Clinical relapse*	Percentage of proved relapses	Percentage of total relapses
Quinine and paludrine	29	18	3	8	*10·3*	*37·9*
Quinine and pamaquin	29	24	2	3	*6·9*	*17·2*

* The criteria of clinical relapse include the history of a rigor and a tertian periodicity of symptoms.

The factors which may have influenced the results have been briefly compared in the two series.

(1) The average intervals between the date of arrival in the U.K. and the date of admission to hospital were for quinine-paludrine 4·8 months, and for quinine-pamaquin 4·1 months.

(2) The probable areas of infection were as follows:

	India-Burma		*Far East (P.O.W.)*		*Other areas*
Quinine-paludrine ..	24	..	4	..	1
Quinine-pamaquin ..	20	..	4	..	5

The fact that each series contains equal numbers of patients who had been in captivity in the Far East obviates any possible bias due to the higher relapse-rate that is to be expected in that group.

(3) The average intervals between treatment and further relapse were for quinine-paludrine 3·6 months, and for quinine-pamaquin 3·7 months.

It was previously thought that paludrine possibly gave a longer period of freedom from relapse than did the combined pamaquin-quinine treatment (Johnstone 1946a). This suggestion is not borne out by the present investigation, in spite of the fact that the dosage of paludrine was larger than in the previous investigation.

(4) As would be expected, no difference was noted in the rapidity with which the temperature fell to normal in the two series, since both received equally large doses of quinine.

CONCLUSIONS

This series is too small for conclusions to be drawn regarding an exact relapse-rate, but the results indicate that paludrine with quinine is not so effective as pamaquin with quinine for controlling further relapses of benign tertian malaria.

The possibility that paludrine may have a synergistic action similar to that of pamaquin has not been confirmed.

The results obtained in the quinine-pamaquin series closely approximate to those previously reported (Johnstone 1946a and b, Malaria Committee 1945), and the quinine-paludrine results are very similar to those found with paludrine alone (Johnstone 1946a), mepacrine (Malaria Committee 1945), and '4430' (Johnstone 1946b).

I wish to thank Major-General Sir Alexander Biggam for permission to publish this paper; and many members of the staff of the Colchester Military Hospital for their help. I am indebted to Imperial Chemical (Pharmaceuticals) Ltd. for the supplies of paludrine.

Reviews of Books

Renal Diseases

E. T. BELL, M.D., professor of pathology, University of Minnesota. London: H. Kimpton. 1946. Pp. 434. 35*s*.

Professor Bell's renown as a morbid anatomist and his special interest in the kidney are well known; his monograph, besides surveying the literature of both medical and surgical diseases of the kidney, contains a detailed analysis of renal cases in a series of 32,360 autopsies, with statistics and numerous case-records. It is primarily an exposition of pathological findings and their interpretations, and it is well illustrated with 117 photographs and 4 colour plates, all original, well chosen, and germane. The section on tubular disease is disproportionately short, perhaps because Dr. Bell is interested mainly in the glomerular basement-membrane (as his good account of the diabetic kidney shows). He hopes, he says, to encourage closer coöperation between pathologist and clinician; and if pointing out the gaps and contradictions in our knowledge of function will help to fill and resolve them, the book should fulfil its purpose. At present we know little of the functional aspects of renal disease, except in essential hypertension. and it is inevitable that the chapters on function and functional disturbances (" extrarenal azotæmia ") should be less satisfactory than the rest. Clinicians will regret the absence of clinical charts or diagrams, and the scanty reference to the grosser biochemical disturbances; and English readers will be surprised to find no mention of the work on nephritis of Ellis, Evans, and Wilson. Despite these minor criticisms the book is a stimulating achievement.

Ranson's Anatomy of the Nervous System

(8th ed.) Revised by SAM LILLARD CLARK, M.D., PH.D., professor of anatomy, Vanderbilt University, Nashville. Philadelphia and London: W. B. Saunders. 1947. Pp. 532. 32*s*. 6*d*.

IT is a difficult task to take over the revision of an established textbook which is stamped with the individuality of its creator. In the 8th edition of " Ranson " Dr. Clark has succeeded in revising and even improving a good book while preserving its distinctive approach to the subject. The matter has been to some extent rearranged, and gross descriptive anatomy is now collected into one section. A new set of illustrations made from parasagittal sections makes it possible for the reader to picture the structures of the brain-stem in three dimensions. The whole book has been revised to include the results of recent research. It is doubtful whether the addition of a chapter of clinical illustrations was worth the space, for the comments are necessarily sketchy and there are already plenty of books dealing with the applied anatomy and physiology of the nervous system. The statement that the posterior columns of the spinal cord conduct sensory impulses serving tactile discrimination and localisation is based on Head's views; but, as Walshe has pointed out, these activities are not forms of sensibility but judgments, and cannot be assigned to tracts in the spinal cord.

Heparin in the Treatment of Thrombosis

An account of its chemistry, physiology and application in medicine. (2nd ed.) J. ERIK JORPES, M.D., reader in biochemistry, Caroline Institute, Stockholm; foreword by Prof. J. R. LEARMONTH, CH.M. London: Oxford University Press. 1947. Pp. 260. 18*s*.

JUST before and during the war, interest in the possible treatment of thrombosis by anticoagulants was stimulated by the production of heparin on a commercial scale in Canada and Sweden. Venous thrombosis, long known as a cause of surgical tragedies, is now recognised as being just as common an agent of sudden death in the medical wards. It is among the dangers of taking to one's bed for any illness; and is responsible, too, for much disability from swollen legs, and for pleural pain and breathlessness. Even when emboli appear it may not be easy to locate their source; the process begins in the deep veins of the calf in almost every instance, and emboli have usually appeared before the leg begins to swell. Tenderness in the calf is taken to be an early sign, especially when accompanied by mild fever.

This book gives an excellent account of the great advances made in Sweden on the study of the chemistry, mode of action, and clinical use of heparin. There is little doubt that heparin shortens the course and diminishes the incidence of complications of venous thrombosis. Jorpes states that, on the average, rest in bed is reduced from 5 weeks to 9 days, and duration of fever from 3 weeks to 7 days, and that further pulmonary emboli rarely occur in patients treated with heparin. His monograph is fully documented and should be carefully considered in Britain, where we have had little opportunity to do much in the way of active treatment for thrombosis along these lines. The amounts of heparin required may cost up to £20 or more per patient, but the Swedish results, if substantiated, would certainly suggest the expense is justified. The cheaper method of using dicoumarol is much more risky and seems to be less satisfactory.

A Descriptive Atlas of Radiographs

(6th ed.) A. P. BERTWISTLE, M.B., F.R.C.S.E. London: H. Kimpton. 1946. Pp. 606. 45*s.*

THE author states that this atlas is primarily designed for the clinician, to whom knowledge is presumably denied by a number of "vociferous radiologists who wish to keep radiology as a closed art, a mystic rite." There are 947 illustrations, most of which are accompanied by a short text. Some of the illustrations are good, some are indifferent, and a regrettable number are of such ancient vintage that text and picture cannot be correlated even by a radiologist. The text is scrappy and makes no attempt at differential diagnosis. Unfortunately some pictures are open to an interpretation different from the author's; accompanying a normal chest picture is the alarming mis-statement that the "older view that the lung markings were due to the pulmonary vessels can be discountenanced definitely." An atlas of X-ray pictures could be very helpful to both student and general practitioner, but this one requires more critical revision.

Buchanan's Manual of Anatomy

(7th ed.) Editor: F. WOOD JONES, D.SC., F.R.C.S., F.R.S., professor of anatomy, Royal College of Surgeons of England. London: Baillière. 1946. Pp. 1616. 45*s.*

THE student, as we have remarked,[1] can make use of three kinds of anatomy textbook—a small concise dissecting manual which can be thrown away when dirty and done with, a larger book giving a coherent account of the systems rather than the regions of the body, and a big work of reference which both he and his teachers can consult at need. "Buchanan's Anatomy" falls into the class of the reference work.

After an interval of nine years a new edition appears under the editorship of Professor Wood Jones, the revision of the various sections having been deputed to members of the department of anatomy at Manchester University. As hitherto, the book deals mainly with topographical anatomy on a regional basis, but there are innovations. Some, such as a series of radiographic illustrations, will certainly be approved; but others may disappoint those acquainted with previous editions. The introductory section on embryology and the descriptive accounts of organogenesis have been almost eliminated, and histology has been greatly reduced—sometimes inconsistently, as when the minute structure of the cerebellar cortex, but not the cerebral, is described. Nearly all the original drawings of Buchanan's Anatomy have been restored, supplemented by almost 200 new diagrams; but the removal of *all* colour (on the ground that colour is unnecessary and sometimes misleading) has made some of the diagrams less effective. The text still contains much of the sort of topographical detail which many anatomists feel might with advantage now be discarded in a reference work used chiefly by students. Certainly there are few items of anatomical topography of which a knowledge may not be of *some* value at *some* time to the practising clinician; but if our physiological colleagues adopted the same principle in planning their curriculum, the medical student would face a textbook of physiology about the size of the *Encyclopædia Britannica*. In any case the medical student is unlikely to make much practical use of such things as the chorda obliqua posterior, the external petrosal nerve (which is stated to be "of doubtful existence"), or the transversus nuchæ muscle.

More eponyms have led to multiplication of terms, which some will feel imposes an unnecessary strain on memory; but the perverse fact is that an eponym often strikes into the mind better than a more logical name. Miss Dobson's biographical notes, at the end of the book, refresh their interest, though perhaps there are rather too many of them.

Textbook on the Nursing and Diseases of Sick Children (4th ed. London: H. K. Lewis, 1947. Pp. 744. 30*s.*).—The new edition of the textbook for nurses, edited by Prof. Alan Moncrieff, has just appeared. It will be welcomed by sister-tutors and student nurses, in orthopædic as well as children's hospitals.

Syndrome cortico-pleural : son étude clinique et expérimentale (Paris: Masson, 1946. Pp. 140. Fr. 160).—The German occupation of France in 1940 postponed publication of this monograph written in French by Prof. J. Skladal, of Prague. An English translation was published by the Cambridge University Press in 1942 (*Lancet*, 1942, ii, 281).

A Short Handbook of Practical Anæsthetics (Bristol: J. Wright, 1946. Pp. 120. 12*s.* 6*d.*).—Surgeon Commander Hoël Parry Price writes a breezy, friendly little book, covering a wide range. Mistakes are acknowledged, and advice based on a wide practical experience is given freely. The chatty style makes easy reading at the end of the day's work, but some of the advice should not be taken too literally by the beginner. Incidentally, the statement that carbon-dioxide absorption "was first used by Snow in about 1887" is only a rough approximation, since Snow died in 1858.

Diseases of the Skin (3rd ed. Philadelphia and London: W. B. Saunders, 1946. Pp. 937. 50*s.*).—Prof. George Clinton Andrews, of Columbia University, New York, deals fully with the commoner skin diseases, and gives enough information about the rarities to stimulate the reader's interest. The chapter bibliographies, omitted from the second edition, have happily returned. The work has been brought right up to date, new illustrations have been added, and redundant matter has been ruthlessly cut. It is a pity that Professor Andrews's just enthusiasm for penicillin has caused him to rate it so highly in the treatment of early syphilis. Many cases of clinical and serological relapses in patients treated solely with penicillin are now reporting at the clinics.

Hæmatological Technique (3rd ed. Calcutta: U. N. Dhur, 1945. Pp. 128. Rs. 8).—Prof. L. Everard Napier and Dr. C. R. Das Gupta describe the standard hæmatological methods followed at the Calcutta School of Tropical Medicine: they are all well-established methods, and no original ones are included. They also give an account of bilirubin estimation and gastric analysis. The blood-transfusion section is somewhat limited and does not mention the Rh factor. The colour plates are unfortunately poor; it would be very difficult to identify the different erythroblasts from these reproductions, and the leucocytes have fared little better. All the same, the full detail will undoubtedly secure a wide local circulation for this book, which is particularly useful for less experienced workers or for training technicians.

Diagnostic electrocardiographique (Paris: Masson, 1946. Pp. 362. Fr. 860).—In this new addition to French textbooks Dr. A. Jouve and Dr. J. Senez provide the beginner with a clear account of the principles and methods of cardiography. The normal tracing and the borderline patterns between normal and pathological are fully described. The arrhythmias receive relatively more attention than conditions of greater clinical importance such as disease of the coronary arteries, pulmonary lesions, and pericarditis. English readers will find this book a sound introduction to the interpretation of electrocardiograms, though they will notice that the old technique is used for chest leads and will encounter a few unfamiliar terms (such as auricular tremulation). The illustrations are good, and the book is a notable achievement under difficult conditions.

3 VITAMINS . . *without reserve*

Because vitamin B_1, vitamin C and nicotinic acid are water soluble factors and are therefore rapidly excreted in the urine, the body is unable to maintain supplies 'in reserve'. Even a brief interruption of the normal food intake results in a combined deficiency of these vitamins . . . a deficiency that may be manifested in the debility, fatigue and generally 'run down' states so often encountered in general practice. The three vitamins are incorporated in 'Nicorbin' tablets to provide a convenient means of oral administration. Given thrice daily, 'Nicorbin' tablets have proved effective in the prevention of even acute deficiency conditions such as beri-beri, pellagra and scurvy.

'Nicorbin' Tablets exert a powerful tonic influence and should be prescribed in conjunction with 'Adexolin' (vitamins A and D) when a general raising of the nutritional level is desired.

Composition. Each 'Nicorbin' Tablet contains :
Aneurine Hydrochloride (vitamin B_1) 1 mg.
Ascorbic Acid (vitamin C) 25 mg.
Nicotinic Acid (P.P. factor) 10 mg.

NICORBIN

In bottles of 25, 100 and 1,000 tablets*

nutritional routine for motherhood

For practical reasons it is rarely possible for the diet of the pregnant or nursing woman to provide *adequate* amounts of all the nutritional factors she requires Three factors especially needed—iron, calcium and vitamin D — are very commonly deficient in her food.

'Caldeferrum' Tablets have the specific purpose of preventing a significant lack of iron, calcium and vitamin D at the time of increased need.

Four 'Caldeferrum' Tablets supply 25 mg. of ferrous iron, 0·5 gram of calcium and 2,000 i.u. of vitamin D This daily dosage is a routine easily adopted by every pregnant and lactating woman.

'Caldeferrum' Tablets are reasonable in price and, being chocolate-coated, are pleasant to take

CALDEFERRUM TABLETS

In bottles of 100 and tins of 1,000

AN ESSENTIAL OF INFANCY

—*vitamin C in precise and stable quantity*

During the first few months of life the infant's minimum vitamin C requirement is approximately 10 mg of ascorbic acid daily. A rational means of ensuring this essential intake is to prescribe one *Infant* 'Celin' tablet daily.

Infant 'Celin' tablets offer a *certain* source of vitamin C in a completely acceptable form, every tablet containing 10 mg ascorbic acid. They are exceptionally stable and retain this potency for two years or more Their anti-scorbutic property is not affected by giving the tablets in warm milk, water or milk feed ; the tablets dissolve readily and cause no digestive disturbance.

Infant CELIN TABLETS

In bottles of 100 and 1,000

It is a pity that Professor Andrews's just enthusiasm for penicillin has caused him to rate it so highly in the treatment of early syphilis. Many cases of clinical and serological relapses in patients treated solely with penicillin are now reporting at the clinics.

Hæmatological Technique (3rd ed. Calcutta: U. N. Dhur, 1945. Pp. 128. Rs. 8).—Prof. L. Everard Napier and Dr. C. R. Das Gupta describe the standard hæmatological methods followed at the Calcutta School of Tropical Medicine: they are all well-established methods, and no original ones are included. They also give an account of bilirubin estimation and gastric analysis. The blood-transfusion section is somewhat limited and does not mention the Rh factor. The colour plates are unfortunately poor; it would be very difficult to identify the different erythroblasts from these reproductions, and the leucocytes have fared little better. All the same, the full detail will undoubtedly secure a wide local circulation for this book, which is particularly useful for less experienced workers or for training technicians.

Diagnostic electrocardiographique (Paris: Masson, 1946. Pp. 362. Fr. 860).—In this new addition to French textbooks Dr. A. Jouve and Dr. J. Senez provide the beginner with a clear account of the principles and methods of cardiography. The normal tracing and the borderline patterns between normal and pathological are fully described. The arrhythmias receive relatively more attention than conditions of greater clinical importance such as disease of the coronary arteries, pulmonary lesions, and pericarditis. English readers will find this book a sound introduction to the interpretation of electrocardiograms, though they will notice that the old technique is used for chest leads and will encounter a few unfamiliar terms (such as auricular tremulation). The illustrations are good, and the book is a notable achievement under difficult conditions.

THE LANCET

LONDON: SATURDAY, MAY 17, 1947

Infection by Injection

There is no form of anæsthesia which does not carry some risk to the patient's life or health; and often the risk is from infection. With inhalation anæsthesia the infection seldom comes from without: postanæsthetic pneumonia is endogenous. But whenever anæsthesia or analgesia is induced by injection there is a chance of introducing fresh organisms into the body; and though cases that "go wrong" are not often published, pathologists are only too familiar with unfortunate complications ranging from subcutaneous abscesses to meningitis.

The risk varies with the route. Intravenous injections are relatively safe, because the natural antibodies and complement of the plasma, aided by the reticulo-endothelial system, eradicate all but highly pathogenic forms introduced in large numbers. The pleural cavity is less well protected, when effusions are present, since in such cases antibody content is apt to be low. Subcutaneous injection, though infection is localised at first, is more dangerous, since the subcutaneous tissues are poorly supplied with blood. But intrathecal injection is the most dangerous of all. Normal cerebrospinal fluid (C.S.F.) contains negligible amounts of protein, and thus no natural antibodies: moreover, it has been noted that when spinal anæsthetics are injected there is usually a measurable rise in C.S.F. protein content, which, though insufficient to provide antibodies, makes the fluid a still better culture medium for organisms, even those not normally pathogenic. Cerebrospinal fluid is in fact so good a medium that an excellent method of isolating pathogens in meningitis is simply to incubate the fluid. From this it follows that spinal anæsthesia demands particularly rigid attention to aseptic technique, and though the records of failure are not at all complete they show that this attention is far from universal. Valuable warnings have been given by Wilson Smith and Muriel Smith,[1] by Frankis Evans,[2] by Vuylsteke,[3] and by Kremer,[4] who described 7 cases of meningitis in a Middle East hospital. Meningitis has also followed lumbar puncture for other purposes, and vertebral osteomyelitis is fairly common; rarely, meningitis complicates caudal anæsthesia.[5] A striking feature of most recorded infections is the presence of organisms of very low virulence, such as *Ps. pyocyanea*, *B. proteus*, fæcal streptococci, and coagulase-negative staphylococci. This again shows that more than ordinary care is required, since such organisms are widely distributed: they need not, indeed do not, come from an infected source. Also they happen to be the group of organisms against which even modern therapeutic methods are unavailing.

These risks are emphasised by the case of Voller *v.* Portsmouth Corporation and others, in which, as we recorded last week, Mr. Justice Birkett awarded damages of £12,000 against the corporation. The patient, a boy of 18, contracted *Ps. pyocyanea* meningitis after spinal anæsthesia with 'Nupercaine.' The judge was satisfied that the nupercaine was sterile, that the ampoule containing it did not convey the infection, and that the infection was not airborne and did not come from the skin of the administrator of the anæsthetic or the skin of the patient. He concluded that the infecting organisms were derived from the apparatus used for the injection—the syringe, needle, bowls of water, or other equipment. In evidence it appeared that the syringe and needle were "sterilised" by a chemical method, including the use of methylated spirit. It was agreed that the general condemnation of chemical sterilisation is of comparatively recent date, though Wilson Smith's 1941 paper in The Lancet was quoted as proof that the grave dangers of sepsis in spinal anæsthesia had been fully ventilated. The accident happened in 1944, but the judge felt that even at that time the technique used should have been better. Certainly there is no longer any excuse for ignorance of the essential factors in such infections. Wilson Smith found that some 40% of 223 unselected specimens of C.S.F. reaching the laboratory for bacteriological examination had been contaminated by non-pathogenic organisms, probably introduced from the "sterilised" water used for rinsing the syringes and needles employed for lumbar puncture. The Medical Research Council's War Memorandum no. 15 (1945) on the sterilisation of syringes, which severely criticises "chemical" sterilisation, states that even methylated spirit may contain organisms, and clearly lays down approved technique for sterilisation. Autoclaving, which is undoubtedly the best method, or adequate dry heat, is not always applicable to glass-metal syringes, though many will stand up to the necessary temperatures. Boiling, however, is within the scope of all; and boiling is perfectly satisfactory provided the syringes and needles do not remain in water exposed to the air, and are assembled with forceps or sterile gloves. It is very easy to contaminate a sterile syringe by immersing a hand in the water in which it has been sterilised.

It is clear that the formation of "syringe services" in all hospitals is urgently needed: that is to say, all syringes should be distributed already sterilised from the theatre. But much more knowledge is necessary, among doctors and nurses alike, of the meaning of "sterility." All should now be aware that there is no safe chemical method of sterilisation; that tap-water is not sterile; that water which has been autoclaved does not remain sterile when exposed to the air; and that the same syringes must not be used both for removing infected material and for spinal anæsthesia. Despite repeated and authoritative statements to this effect, individuals will always be found to quote their own immunity from catastrophe as proof of the unreliability of laboratory experiments and clinical experience. There is no room, however, for such self-satisfaction, and we trust that this Portsmouth case may lead to a continuous effort to re-educate nursing staff and doctors on the penalties of laxity.

Stimulus to Intestinal Peristalsis

I-SO-GEL, a granular preparation of certain dried mucilaginous seeds, has the property of reproducing the normal stimulus to intestinal peristalsis by increasing the intestinal bulk, through absorption of water in the alimentary canal.

I-SO-GEL contains no purgatives and is a purely natural laxative with a smooth mechanical action, specially suitable for the constipation of diabetes.

It is valuable also in mucous colitis, dysentery, hæmorrhoids, and intestinal flatulence. After the performance of colostomy, I-so-gel gives excellent results by solidifying the fæces.

In bottles at 4/6 *and* 16/10 *each, including Purchase Tax*

ALLEN & HANBURYS LTD · LONDON · E·2

TELEPHONE: BISHOPSGATE 3201 (12 LINES) TELEGRAMS: "GREENBURYS BETH LONDON" infection the drug is of little value.[14] Benadryl is a cerebral depressant, and minor toxic effects such as lassitude, drowsiness, and giddiness are common, even with therapeutic doses of 25–50 mg. Other side-effects reported include hot flushes, dryness of mouth and nose, nausea, aggravation of existing headache or asthma, and, paradoxically, insomnia. Nervousness, difficulty in coördination, and epileptiform movements were noted in a boy aged $3^{1}/_{2}$ years being treated for hay-fever.[15] A young woman of 26 with dermatitis reacted to the drug in a shock-like manner,[16] and a girl of 18, who appears to have helped herself to 2000 mg. of benadryl in 48 hours, developed severe mental confusion and disorientation.[17] In view of these rare but alarming manifestations it is well to remember that histamine acid phosphate, in doses of 0·5 mg. intravenously, is a specific antidote to benadryl.

At about the time when benadryl was being introduced Mayer and his colleagues[18] produced 'Pyribenzamine,' which again closely resembles antergan in composition. This drug can protect animals against 60–120 times the lethal dose of histamine given intravenously, and so is about a hundred times as powerful as the early anti-histamine drugs Friedlaender and his colleagues[19] found that, in guinea-pigs, five or six times the lethal dose of histamine was needed to kill all animals protected with 3 mg. per kg. of benadryl or of antergan, whereas the same dose of pyribenzamine protected some animals against thirty-five lethal doses. Pyribenzamine has been highly effective in vasomotor rhinitis and hay-fever; it has given good results in urticaria and angioneurotic œdema, and has relieved itching in dermatitis; moderate relief has been claimed in chronic allergic rhinitis; but in asthma the results have again been poor.[20] The side-effects of pyribenzamine are similar to those of benadryl and are fairly common but mild.

Lately, Halpern and his colleagues[21] in France have introduced yet another group of anti-histamine drugs, this time derivatives of thiodiphenylamine, known as '3015RP' and '3277RP.' Experimentally these have been shown to be less toxic and very much more potent than the antergan group, and they have been successfully used in cases of urticaria.

Here, then, we have some new recruits to the élite class of specific remedies, and sufferers from hay-fever and the like are duly thankful. But it should not be forgotten that the anti-histamine drugs are at best only palliatives; they do not remove the need for attempts to recognise the allergen and eliminate it or to desensitise the patient. Nevertheless, in the hands of the research-worker, they may well lead to fundamental advances in the study of allergy. The drugs can be used to distinguish weals caused by release of histamine from those produced in other ways[22]; or to decide what elements of anaphylaxis are attributable to liberation of histamine from the tissues.[23] It has been found, too, that the drugs block all the actions of histamine except its stimulation of gastric acid secretion. This makes it possible to inject large doses of histamine plus an antagonist in experimental studies of peptic-ulcer production.[24] It also throws some light on the mode of action of the anti-histamine drugs. The mechanism is still doubtful; one view, based on the observation that the amount of histamine antagonised bears a quantitative relationship to the amount of anti-histamine drug injected,[25] is that the drugs compete with histamine for a site of action or receptive substance, in the same way as *para*-aminobenzoic acid competes with the sulphonamides.

Matters of Life and Death

We welcome the appearance of the text of the Registrar-General's *Statistical Review* for 1938 and 1939,[26] both for its account of the vital events of the last years of an uneasy peace, and even more for its commentary on the first fruits of the Population (Statistics) Act of 1938, whose inquisitorial nose was so firmly tweaked by Sir Alan Herbert. We may share A.P.H.'s distaste for the intrusion into private lives entailed by the questions about the dates of marriage and the birthdays of children, but this is certainly a case where the ends justify the means. These ends are quite clear. This country now faces the problem of an increasing proportion of older people with declining numbers of the young adults on whose working capacity the future depends. The problem stems from the low birth-rate between the two wars, culminating in 1939 when, with a rate of 15 births per 1000 of the population, we shared with France the melancholy distinction of the lowest rates in Europe. The post-war boom in the birth-rate, if it continues, will of course have its ultimate effect; but it will not tide us over the interim period until the children born in recent years attain maturity. As a profession we can do two things to minimise the seriousness of the situation now developing: we can blunt the worst effects of the inter-war lapse by reducing the mortality among potential mothers, and we can try to prolong the useful and happy working lives of older men and women. On the larger questions involved we must echo the cri-de-coeur of the R.A.F.—"give us the gen." For without the "general information," which only vital statistics can provide no decisive action is likely.

The marriage habits of a country tend to reflect the psychological reaction of the people to the social and economic conditions of the time. Marriage-rates, which were depressed during the slump years of 1926 and 1930–32, were rising steadily before the late war. Even more important was the fact that people were tending to marry younger. The favourable marriage position is indicated by a fall in the proportion of spinsters remaining unmarried—19% at age thirty and 11% at forty in 1938, instead of 32% and 20% at these ages in 1911. The reverse of the medal, however, is less cheerful. The new method of birth registration provides statistics to show that one in seven of the children now born in this country is the

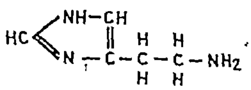
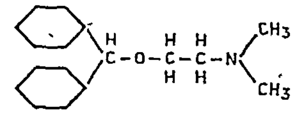
The Anti-histamine Drugs

HISTAMINE, which can be looked on as the amino-acid histidine minus a molecule of CO_2, was first isolated from ergot by **BARGER** and **DALE** in 1910, but has since been found in many other plants. Its astonishingly wide and powerful pharmacological activity had been extensively studied before **DALE**, **BEST**, and their colleagues at the National Institute of Medical Research showed that it was a normal constituent of all body tissues, especially plentiful in the lungs.[1] **LEWIS** preferred to call the active substance obtainable from tissue cells "H-substance," but it seems probable that histamine itself is normally held within cells which are insensitive to its action, and that when it is liberated by trauma, infection, or toxins it produces various local and constitutional disturbances by acting on responsive cells in the blood-vessels, bronchioles, gut, and so on When injected parenterally histamine can produce effects closely resembling many familiar syndromes, including anaphylaxis, traumatic "shock," the collapse following burns, and the "allergic" maladies urticaria, asthma, and hay-fever. It may be that in all these conditions an escape of histamine, either free or in loose molecular combination, is an essential factor. On this view, when the specific antibodies in an allergic person's cells react to a foreign protein, histamine is liberated and causes spasm of smooth muscle or capillary dilatation. Man possesses highly efficient mechanisms for the destruction of histamine, and can detoxicate 10 mg. an hour given intravenously. The process seems to take place partly in the liver and partly in the various tissues which contain the enzyme histaminase (kidney, small intestine, &c.). Histamine has proved ineffective therapeutically, and attempts to build up an active immunity to histamine by injecting increasing doses have failed, because histamine does not produce antibodies, even when linked with iodine or bromine. Research chemists have therefore sought for anti-histamine agents: barbitone, the potassium salts, ascorbic acid, hesperidin, and ethylene disulphonate have in turn been lauded and then disparaged; by 1932 the list of substances or methods numbered 165 items. The amino-acids histidine and arginine were found to inhibit some of the effects of histamine in the guineapig and in isolated tissue, but they are too toxic and too weak to be useful.

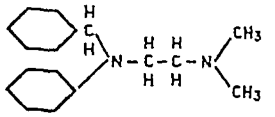
The successful line of research dates from 1937, when **UNGAR**, **PARROT**, and **BOVET**[2] in France found that some phenolic ethers are potent antagonists of histamine These compounds had previously been synthesised and shown to possess sympatholytic activity by **FOURNEAU** and **BOVET**.[3] The most effective compounds in this series were named '929F' and '1571F,' and the claims made for them were confirmed, but they proved too toxic for clinical use. However, it soon became clear that phenolic ethers could be found which were no less active and of reasonably low toxicity. Two of them, 'Antergan' and 'Neoantergan,' were strikingly effective in protecting guineapigs against the bronchospasm caused by atomised histamine, and they have been widely used in France since 1942 in the relief of allergic disturbances. Neoantergan is better tolerated than antergan and can therefore be used in higher doses. **FEINBERG** and his colleagues[4] sum up their experience of neoantergan thus: "In seasonal hay-fever the drug was of benefit to 39 of 60 patients; in perennial rhinitis to 8 out of 10 patients; and in asthma to 1 of 5 patients." The ineffectiveness of this drug in asthma is characteristic of all the synthetic anti-histamine drugs so far tried On another page Dr. **HUNTER** confirms the excellent effects of neoantergan in urticaria and angioneurotic œdema. He also describes the side-effects noted—usually no worse than a mild lassitude provided the drug is given only by mouth. Oddly enough, as Dr. **HUNTER** points out, neoantergan is a potent local anæsthetic and also exerts a quinidine-like action on heart muscle.



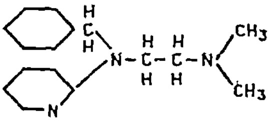
HISTAMINE



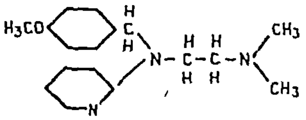
BENADRYL



ANTERGAN



PYRIBENZAMINE



NEOANTERGAN

Two years ago, **LOEW** and others[5] in the U.S.A. introduced another of the phenolic ethers—β-dimethyl-aminoethyl benzohydryl ether hydrochloride, or 'Benadryl'—which quickly established itself in therapeutics. The formulæ show how close is the chemical relationship between this and antergan. **FEINBERG** et al.[4] have reported benefit from benadryl in 80% of patients with sensitisation dermatitis. Others[6-10] have recorded relief from hay-fever in about three-quarters of their cases, but **FRIEDLAENDER**[11] has been less impressed by its effects in this condition. He also remarks that the conspicuous success of benadryl in urticaria suggests that histamine may be a more important factor in urticaria than in other allergic conditions. In perennial vasomotor rhinitis 33 of 47 patients were benefited.[13] Temporary improvement has been reported in chronic hyperplastic ethmoiditis; the polypoid tissue retracts and disappears, and the purulent discharge diminishes, but only so long as the drug is being taken.[7] In purely allergic asthma, even under the most favourable conditions, the results obtained from benadryl are disappointing—only about 1 in 10 cases derives benefit[13]—and in bronchial asthma with secondary

31 volunteers who, acting as controls, received normal broth-saline intranasally, were uniformly negative; but of 20 who received normal egg-fluids, 1 developed a definite cold and 3 had doubtful colds. Possibly these colds were acquired before isolation, and became manifest after a rather long incubation period; but fortunately such "unauthorised" colds have been few. Experience has shown that in 70% of induced colds the incubation period is two to three days, though it may be as short as twenty-four hours or as long as six days. The volunteer seems to be equally susceptible whether he has had a cold within the past month or has been free for over six months. A possible, though unlikely explanation is that the filtrates contain a virus different from that currently producing natural colds; or a general immunity may in some be more important than a transient specific immunity.

DRINKER'S PROGRESS

ALCOHOLICS Anonymous is an American fellowship of heavy drinkers, some cured, some newly joined in the hope of cure. New members who live in remote places get a steady flow of helpful letters, mostly by air-mail, from others who have been through a like experience and who talk their own language; town members, whenever their longing for a drink becomes unbearable, can ring up a cured member, at whatever time of the day or night, and are encouraged to talk with him or go walking with him. Some pieces of advice are given to all who join: they are told that "A.A. will work if you want it to work," and are urged to say to themselves on waking, not that they will give up drink, but that they will not drink for this one day. They are taught to eat sweets to replace the sugar which they were previously getting from alcohol. "The technique," one recovered alcoholic writes[1] ". . . was not to push, or even to lead, but to walk with you and offer you something you need—if you want to accept it." A.A. claims 75% of successes in the treatment of its members: half of them are able to stop drinking at once, and a further quarter stop after one or two lapses; a quarter fail, or lose touch with the fellowship. There is no charge: a sincere desire to stop drinking is the only thing required of new members.

Among other work, A.A. has provided research material; and two monographs,[2] reprinted from the *Journal of Studies on Alcohol*, have lately thrown light on alcoholism from data made available by the fellowship: one is an analysis of the results of a survey into phases of the drinking habits of alcoholics conducted through the *Grapevine*, the national organ of the Alcoholic Foundation, New York; the other sets out detailed histories and the psychological findings in "compulsive" drinkers, most of whom were members of the fellowship. The *Grapevine* survey was made by means of a questionary which members of the organisation were asked to fill in, so that it could be learnt at what ages those events occurred which, in the experience of recovered drunkards, are critical turning-points. Dr. E. M. Jellinek's analysis of the replies is illuminating in its reasoned rejection of some widely held opinions and acceptance of others. Solitary drinking at an early stage, and bouts with subsequent amnesia for what happened in them, are ominous signs: about two years after the first of such amnesic bouts the man usually finds that he is constantly drinking more than he had intended; this is the crucial phase. He next begins to rationalise his conduct ("I can stop it if I want to," "I never get drunk without a good reason"), and thenceforward, unless circumstances prevent him or insight develops, his course is set for steady alcoholism. About a year after the process of rationalisation has begun (at the average age of 30) he starts taking a drink first thing in the morning, so that he can face the day before him. About a year, or perhaps as long as three years, after this he begins to indulge in bouts of drinking without regard to his family, work, or other obligations. Solitary drinking, which had been practised sooner or later by 90% of the ex-alcoholics who answered the questionary, was closely associated with "antisocial" acts—quarrel-picking, brawling, violent jealousy. A still later phase was characterised by tremors and indefinable fears: this usually developed after about another three years of excessive indulgence. Two years later the subjects realised that they "were licked"; they could not control their drinking or rescue themselves from their degradation. It was after they had reached this nadir that they got in touch with Alcoholics Anonymous. There were of course wide variations in the length of interval between these phases in the drinking history of individuals, and in a few cases the order in which they developed was atypical, but in most the drunkard's progress had been towards a predictable downfall; the length of time between prodromal symptoms and the lowest point before recovery was, in the shortest instance in the survey, 12 years, and in the longest, 18 years. Jellinek concludes his analysis with the design of a much more comprehensive and skilful questionary which could be used in any study of the history of recovered alcoholics to discover significant prognostic factors.

The other study fills a surprising gap in psychiatric knowledge by providing authentic and detailed life-histories of a number of drunkards, most of them well-educated men and women from upper social and economic levels. The histories make gloomy but absorbing reading; and though the dénouement is often satisfactory enough for the quondam drunkard, he leaves in his wake, as he progresses towards ultimate reformation, such a trail of misery as to put the reader in mind of that Mr. Wilson whose story was once heard by Joseph Andrews and Parson Adams.

Psychological tests given to 47 of these alcoholics consisted of the Rorschach inkblots, the vocational interest indicator of masculinity and femininity, and the level of aspiration test. The results showed the alcoholic to be an unstable, restless person who does not withdraw in the face of difficulties or adjust to them, but treats them as a challenge; he takes chances, refuses to recognise his inadequacies, and denies any conflict within himself. He exposes himself to the risk of failure, inviting rather than avoiding trouble.

GESTATION PERIODS

THE whole gamut of mammalian gestation periods, from the elephant (about 620 days) to the opossum (about 12 days), is accurately recorded in the second edition of Kenneth's[1] comprehensive and well-documented tables. His figures offer some support for the belief of Aristotle and William Harvey that the length of pregnancy is directly proportional to the size or weight of the animal, but several exceptions must be admitted—compare the hippopotamus (about 240 days) and the lion or tiger (about 110 days) with the human (280 days). Needham[2] maintains that despite such discrepancies the log. of the adult weight—or, better, the birth-weight—of an animal is directly proportional to the log. of its gestation period.

Among several figures for human gestation periods Kenneth gives the longest recorded menstruation-labour interval as 351 days and the shortest as 196 days.

product of extramarital conception and that nearly 30% of all mothers conceive their firstborn out of wedlock. Of married women under twenty, between 40% and 50% were pregnant before marriage; and lest it be thought that the under-twenties are in any way worse than their older and theoretically better sisters, it is pointed out that taking all extramarital conceptions as a whole, whether later legitimised or not, the rates of irregular maternity are highest among women of twenty to twenty-four (36·0 births per 1000 unmarried women), gradually decreasing to a rate of 4.0 per 1000 in those over forty. The extensive range of these sexual irregularities indicates that despite the availability of contraceptive methods "a large proportion of our children continue to arrive other than at the conscious and deliberate intention of their progenitors." The medical implications of these facts are seen in the statistics of infant mortality. In the first days of their lives the mortality-rate among illegitimates is more than twice that among legitimates. The precise causes of death responsible for this difference are hard to assess owing to the vagueness of certification in conditions like congenital debility and enteritis; but syphilis is clearly one of the principal reasons for disparity, followed by diarrhœa and enteritis, prematurity, and congenital debility.

Despite a general improvement in mortality-rates among the adult male population, there has been a dramatic rise in the wastage from cardiovascular disease of the degenerative type in men over forty. Comparing the male and female death-rates in 1939 with those of 1921–30, we have the following percentage increases in the death-rates from coronary and myocardial disease, arteriosclerosis, and senility:

	45–	*50–*	*55–*	*60–*	*65–*	*70–*	*75+*
Males ..	+130	+157	+137	+115	+83	+58	+39
Females ..	+ 78	+ 76	+ 79	+ 81	+78	+53	+32

It is perhaps significant that these excessive rates weigh most heavily upon men who were between twenty-five and forty-four years of age during the war of 1914–18. Similar dramatic increases are apparent in the standardised death-rates in cancer of certain sites; mortality from lung cancer increased by 78% from 1931–35 to 1939, cancer of the testis by 14%. Despite the difficulties of certification in deaths from multiple causes among the aged, these events can hardly be explained entirely by improvements in diagnosis or changing fashions in nomenclature. They remain as a challenge to further research. In that research the demand will be always for more facts, and these facts must come from the general practitioners of this country. "A death rate," as WILLIAM FARR said, "is a fact, anything beyond this is an inference"; but the specific death-rate for any disease is a fact only if its certification is at once complete and accurate. At both ends of the age-scale, death certification lacks the precision it has attained for childhood and young adult life; yet the importance of adequate information about these periods is surely manifest. Let us look, therefore, upon the certification of death not as a chore demanded by a bureaucratic machine but rather as an opportunity to contribute to the science of medicine.

Annotations

IN MEMORIAM

THE young have eyes only for the road ahead; but as they grow older they begin to glance back, and finally they stop to study quite openly the way they have come. This is the true luxury of age; and happy is he who can relish it. In his imagining each lingers over something different, for there are many roads and many eyes; but the best-remembered images usually have this in common, that they spring from an experience shared. A common aim, a common interest, or perhaps a common peril has swelled the store of happy experience. For those who served in the war that is past the strange experience is not yet clear in its full form and size. But one thing is certain: the memory will continue. What will be best recalled is not the dragging days of boredom, the long hours of work, or the brief encounters with danger, but those with whom these times were spent. Not all returned; and some came back scarred by battle. General Hood has appealed [1] for a memorial to the two thousand men of the Royal Army Medical Corps who were killed; it is to be a living memorial, to help the injured and the relatives of the dead. Those who served will need no second bidding, and in answering this call they will brighten their memories; while those who did not serve will wish to give in thanks that they were served so well.

THE COMMON COLD

THE common-cold research unit at the Harvard Hospital, Salisbury, has now been working for ten months, and the 2000 volunteers who came forward after the recent newspaper appeal have assured a supply sufficient for the rest of this year. Results of initial experiments were given to the epidemiological section of the Royal Society of Medicine at a meeting in Salisbury on May 2.

As we have already noted,[2] volunteers on arrival are isolated in pairs and observed for three days, in case they are in the incubation period of a cold. On the fourth day they are inoculated with test or control material. In work of this character, where the experimental animals are able to express subjective impressions, it is of the first importance that the doctor diagnosing the induced colds should be unaware of the nature of the inocula. The period of trial is ten days, of which six remain for the development and assessment of colds. Since the unit can take only 12 pairs of volunteers at fortnightly intervals progress by this method is bound to be slow; and the first objective is the discovery of some more convenient test for the presence of the "cold" virus.

Attempts to cultivate the virus, which have occupied most of the investigators' time, are still only in the preliminary stages. Washings from the nose and throat of persons in the first or second day of a cold have been found to provide a satisfactory source of virus. Bacteria are removed from the washing by filtration through collodion membranes with an average pore-diameter of 0·7μ. Of 64 volunteers inoculated intranasally with filtrate, 28 developed definite though usually mild colds, 11 developed doubtful colds, and 25 proved refractory. Of the nine filtrates that have been prepared, all have induced colds in some of the volunteers. Even diluted to 1 : 100 the filtrates still provoke colds, though with less certainty. The filtrates can be stored for at least three days at 4°C without apparent deterioration, for at least twenty-seven days at −10°C, and for at least four and a half months at −76°C. Preliminary filtration studies suggest that the size of the virus is under 150 mμ, but over 30 mμ; but the lower size-limit is tentative because the starting material was probably of low titre.

fatal charge for miles), walls, hedges, river banks, and ponds are dangerous: but apparently the heart of a wood is fairly safe. Finally, the person who is going to be struck is better wet than dry: for wet clothing will short-circuit some of the current. In the same issue Dr. T. H. White and his wife report the case of two children in England, sheltering under one umbrella beneath a high wall, and standing in a pool of water. They were struck and killed outright.

> Mrs. White herself had a strange experience from secondary discharges when lightning struck the ground some 60–70 feet from the room in which she was with her 15 months' baby. The room filled with a great flame, as it seemed, but she heard no sound. She felt as though the floor and ceiling were giving way, and seemed to see the baby screaming and debris falling. She was numb and stiff from the chest down and tingling all over. She remembered beginning to scream, and next remembered finding herself on a neighbour's veranda 200 yards away, without knowing how she got there. The numbness subsided, but the tingling became worse and she had a violent headache. The baby was dazed and pale for about five minutes after reaching the neighbour's house, but then recovered and walked about. Three hours later Mrs. White was still suffering from shock with dilated pupils and stiff limbs, but with a slow pulse. She had no burns or bruises. Next morning the baby was normal and so was she except for some stiffness of the neck.

She and her husband comment that a house with a galvanised-iron roof and a veranda all round closed in with mosquito gauze should be nearly lightning-proof, since it forms in effect a Faraday cage—a closed conductor inside which there can be no charge.

THIOURACIL AND THE HEART

As a remedy for heart-failure and angina pectoris total thyroidectomy has never found much favour in Britain; for it is an irreversible procedure with a considerable operative mortality. Not unnaturally, thiouracil has lately been suggested as a substitute. Raab,[1] who attaches importance to adrenergic discharges in the pathogenesis of angina pectoris, reports favourably on thiouracil, ascribing its efficacy to "a diminution of myocardial sensitivity to heart-anoxiating, angina-producing epinephrine and sympathin discharges." Of his 10 patients, 7 responded satisfactorily, 1 was slightly improved, 1 showed no improvement, while 1 died as the result of a coronary occlusion during treatment. The dose of thiouracil in the early stages ranged from 0·4 g. to 1·2 g. in divided doses daily, with 0·1 g. as a daily maintenance dose.

A very different view is taken by DiPalma and MaGovern,[2] who hold that thiouracil is indicated in angina pectoris only when the basal metabolic rate is raised, or as a test in the selection of patients for thyroidectomy. Their conclusions are based upon a small series of 8 patients, of whom 6 had had coronary occlusion and 1 had severe rheumatic aortic incompetence; in only 1 is the result described as excellent, and in 5 it was poor. The daily dose of thiouracil was 0·6 g., given in divided doses, and the duration of treatment ranged from three weeks to over a year. In 4 cases treatment had to be stopped because of toxic reactions—skin rashes or dyspnœa. During treatment 1 patient had a coronary occlusion, and 1 developed dyspnœa attributed to water retention. This latter reaction to thiouracil has already been described[3]; and DiPalma and MaGovern refer to a patient with hypertensive heart-failure, not included in their series, in whom administration of thiouracil was followed by recurrence of subcutaneous and pulmonary œdema. On the other hand, Sharpey-Schafer[4] has used thiouracil successfully in patients with severe congestive heart-failure who had not responded to treatment by rest in bed, digitalis, and organic mercurial diuretics. He divides his cases into two groups: low-cardiac-output failure (hypertensive and valvular heart disease), and high-cardiac-output failure (heart-failure with emphysema). In the former thiouracil decreased arteriovenous oxygen differences and the resting oxygen consumption, while in the latter it reduced the high cardiac output to normal through a decrease in oxygen consumption and an increase in the arteriovenous oxygen difference. Dosage was high—1–3 g. daily for up to 275 days. It is clear that further work is required for the assessment of thiouracil in both angina pectoris and congestive heart-failure.

NEW OUTLOOKS ON INDUSTRY

> ". . . to know, as Cromwell's picked captains knew, 'what they are fighting for, and to love what they know,' to be informed and consulted about the job and their part in it. It is no longer sufficient that a man should 'do what he is — well told,' and leave the worrying to the 'bosses.'"

Mr. H. E. G. West,[1] managing director of Newton Chambers & Company, writing on the conversion of management into leadership, heads his article "A Matter of Confidence"; and confidence only comes when the men realise that the management is treating them sincerely. Such sincerity, initiated at the highest level of management, must be transmitted to the lower levels. "I believe," he says, "joint consultation is possible in every industrial unit at almost every level." If the men are to know what they are doing they must be given some insight into the work of the firm. His firm has arranged short training courses for groups of 15–20 men and women returned from the Forces; this "reinstatement week" gives them a chance to see the entire background of the industry and its relation to the firm's activities. The young people entering the firm from school have the various departments and activities explained to them by senior managers and executives; business-training pupils have been asked to "log" the instruction given in their first month and the impression the managers made on them. "The comments in those journals were often illuminating, indeed salutary, to the lecturers." Training of these kinds have spread understanding and good will, and have no doubt had other good results, raising self-respect and encouraging initiative; but training courses, Mr. West points out, will not supply deficiencies in transport, canteen service, ventilation, heating, lighting, tools, clothing, health services, or safety precautions. Dr. R. S. F. Schilling,[2] writing on the next steps in industrial health services, brings this home. The shrinking manpower in dirty and unattractive industries—notably the mining, foundry, and textile trades—and shorter hours of work, will oblige management to depend for increased production on more mechanisation, better layout, and improved methods. Toxic and dust hazards, once the doctor and chemist have made their nature clear, must be prevented largely by the engineer. The selection of workers for various tasks, and accurate job-analysis, falls to the psychologists; human relations must be studied with the help of social scientists and welfare officers.

Mining presents special problems: in the three years 1943–45 accidents to miners causing incapacity for more than three days came to more than 170,000 yearly; and nearly 1900 miners were killed in the three years by accidents at work. In 1944 more than 12,000 miners or their dependants were granted compensation for industrial diseases, the most important being pneumoconiosis, "the beats," and nystagmus. It is hardly surprising that many of the older miners discourage their sons from entering an occupation with such risks. Dr. Schilling suggests that a comprehensive health service

The medicolegal importance of such cases is obvious; the law has indeed recognised a gestation period of 331 days.[3] The average period is 280 days, but the observations of Hotelling and Hotelling [4] and Anderson et al.[5] indicate significant racial differences; the average gestation period of the American negro, for example, is a few days less than that of the white American.

Kenneth notes several instances of the "fertilisation-labour" interval—which should be termed the "coitus-labour" interval because the exact time of fertilisation of the ovum cannot be readily determined in the human subject. The coitus-labour period is a more accurate approximation to the absolute length of pregnancy than the menstruation-labour interval, often and conveniently used in obstetric practice. Further information about the coitus-labour interval could be gained from studies on artificial insemination or the correlation of a single act of coitus with the result of an Aschheim-Zondek or similar test some 3–4 weeks later. Venning [6] has shown that adrenal corticoid excretion is increased in the first trimester of pregnancy. If corticoids, in addition to hormones derived from the chorion or the anterior lobe of the pituitary, are excreted in the urine shortly after implantation and embedding of the ovum, the elaboration of more sensitive tests for their identification might well replace the Aschheim-Zondek and similar tests as the earliest proofs of pregnancy.

A NEW CORONARY VASODILATOR

A DRUG capable of active coronary vasodilatation without reduction of the blood-pressure or increase in the pulse-rate would clearly be valuable. These properties are claimed by Anrep and his colleagues [7] for khellin, the active principle of *Ammi visnaga* Lam. This plant, which grows wild in Eastern Mediterranean countries and in Arabia, has for centuries been a popular remedy in Egypt for renal and intestinal colic; and in 1934 the tincture and decoction were included in the Egyptian pharmacopœia.

The active principle, a di-methoxy-methyl-furano-chromone, has been carefully investigated. In heart-lung preparations from dogs the minimal active concentration was found to be about 1 : 2,000,000, while concentrations of about 1 : 200,000 produced a three to fourfold increase in coronary blood-flow. The same effect was obtained in the intact animal, provided the dose did not exceed 2 mg. per kg. body-weight. It is thought that khellin acts directly on the muscle-fibres of the blood-vessels and that the apparently selective response by the coronary vessels is due to their particular sensitivity. The drug has now been used in over 150 patients; and with single or repeated doses of 100 mg. intramuscularly, or with 50–100 mg. by mouth thrice daily, the results are said to be "extremely encouraging." Among 38 patients with angina pectoris the response was satisfactory: in 13 who received 40 mg. thrice daily, one to three days being required for the full effect; of 9 treated by intramuscular injections of 90 mg. daily, or 120 mg. on alternate days, 8 responded well; while of 16 severe cases treated by a combination of intramuscular and oral therapy, 14 responded well. This dosage was given daily for 2–5 weeks to 8 patients with coronary thrombosis; and these too were apparently benefited. Full trial of the drug is thus justified.

That khellin may have further uses is suggested by the observation that after a single intramuscular injection of 200–300 mg. "complete and prolonged relief" was obtained in 41 out of 45 patients with severe bronchial asthma; and even this fairly large dose had no effect upon the blood-pressure. It has, moreover, relieved attacks resistant to adrenaline and aminophylline. Whether, as suggested, khellin is safer than aminophylline, is not yet certain, for experience with it is so far small. If, however, khellin is to come into general use preparations of it must be purified and standardised; for there is some evidence that the impurities in *Ammi visnaga* may be toxic.

PLEURISY AND TUBERCULOSIS

IN 1911 Koster and Allard published a classical report [1] indicating that "primary" pleurisy with effusion was followed in nearly 50% of cases by pulmonary tuberculosis. Later investigations, however, have yielded less alarming figures, and a study by Lassen and Kjaergaard in 1935 suggested that only some 8% become tuberculous. Opinion on the best treatment is still divided, as is shown by two recent papers. In one, Jervell and Istre [2] found that of 143 cases of primary pleurisy, observed for 1–5 years, pulmonary tuberculosis developed in 11, with 4 deaths. Apart from the effusion the radiological findings were negative in 100, of which 3 subsequently showed signs of pulmonary tuberculosis. There was no subsequent history of tuberculosis in any of the 24 cases showing hilar adenitis, or of the 28 showing homolateral pulmonary infiltration. Tuberculosis did, however, develop in 2 of the 3 with pulmonary infiltration on the side opposite to the effusion, and in 6 of the 7 with bilateral infiltration. Jervell and Istre conclude that the patient with a primary effusion need very rarely be submitted to the hardships of an artificial pneumothorax.

This is not the view of Nilsen,[3] who has followed up 138 cases for an average of $4^1/_2$-years. His routine treatment of these patients consisted in aspiration of the fluid, with air replacement at atmospheric pressure. Of the 138, 18 developed some form of tuberculosis, which in 8 proved fatal; and in more than half of these 18 cases the disease developed within a year of the pleurisy. Nilsen, though not suggesting a sustained pneumothorax for every case of tuberculous pleurisy with effusion, advocates this treatment when there is homolateral infiltration, or when the sputum contains tubercle bacilli and there is no evidence of contralateral infiltration.

ADVICE ON THUNDERSTORMS

THE *East African Medical Journal* [4] is usefully confident about behaviour in thunderstorms. The best place to be, it affirms, is inside a house with all doors and windows closed and not too near the fireplace; "to seek further safety in a cellar or clothes cupboard is not necessary." Lightning is apt to come through an open window with wind and rain. If a chimney is struck, bits of masonry and metal may be blown out into the room and cut an occupant's legs. The neighbourhood of the main switch and meter are also best avoided, since they may be blown up and burnt out if lightning strikes the supply wires; and it is advised that the lead-in wire from the aerial to a radio set should be fitted with a switch so that both may be earthed when thunder is about.

Open windows, doorways, and verandas are dangerous. If it is impossible to seek sanctuary in a house or a closed motor-car any solid shed will do, especially if doors and windows can be shut. A shallow shed with one side open is said to be little safer than the open air. Crowds of people and herds of cattle seem to be mildly attractive to lightning. If one is far from home or shelter when the storm breaks the best plan, it seems, is to lie down in a ditch or hollow until it is over; but the writer of the article had no hope that this advice would be widely followed. Single trees, wire fences (which may carry a

colonies there are islands of comparative cleanliness where a start with hope of extension could be achieved.

Until a fully comprehensive operation can be launched, the best line is to concentrate on making one class of African reasonably clear—that is, the educated African. If these are taught, in the schools and universities, and by all means possible, how to dislike and avoid venereal disease and where to get treatment if they become infected, then slowly, as the clerks, telegraphists, and printers emerge from their technical training, they will also be "V.D.-conscious." Then one day, perhaps, gonorrhœa will be regarded as an unpleasant disease to be rid of and not as a rather annoying variant of normality.

MORE PITFALLS IN DIAGNOSIS OF ANGINA

THE fact that cervical arthritis may cause precordial pain has been known for some time,[1] and two American workers[2] report a series of cases in which angina pectoris was closely simulated by ruptured intervertebral disks in the lower cervical spine. Of 30 patients with this lesion, there were 7 in whom the differential diagnosis between ruptured cervical disks and coronary disease had to be carefully considered. These subjects had precordial pain, sometimes radiating to the shoulder and into the arm. In some this was associated with exertion and accompanied by dyspnœa; in others the pain occurred at rest but was so severe that, being accompanied by dyspnœa, it immediately suggested myocardial infarction. Only by careful examination was the possibility of coronary disease excluded. In 3 the diagnosis was confirmed at operation, which revealed a herniated nucleus pulposus compressing the nerve-root, and the removal of the herniated nucleus led to complete relief of pain. In a 4th case the precordial pain occurred only after operation, but was finally relieved by neck retraction.

In establishing the diagnosis the important points are a history of trauma to the neck, and the radiation of the pain which is sometimes rather diffuse. With a ruptured disk, pain which is related by the patient to exertion turns out to be due to strain on the neck or shoulder: another useful guide is a history of repeated attacks of numbness in the fingers. Examination may show wasting of the pectoral muscles, or of the biceps, triceps, or small muscles of the hand. The pain may be reproduced by pressure on the head or over the affected nerve root in the brachial plexus, and radiography often reveals characteristic changes in the spine. Where the diagnosis is still in doubt the lack of response to nitrites is a pointer.

Why a ruptured intervertebral disk should cause precordial pain is still unexplained, but it is noteworthy that in one patient in this series pressure on the annulus fibrosus at operation reproduced the precordial pain of which he had been complaining.

LOCUST BEANS IN INFANTILE DIARRHŒA

A METHOD of treating infantile gastro-enteritis, which has been favourably reported on in Italy, uses a flour made from the beans of *Ceratonia siliqua*, an evergreen tree of the order leguminosæ, which has spread from the Levant throughout the coasts and islands of the Mediterranean as far as Spain. It was introduced into England in 1570, and its cultivation in London is recorded in Gerard's *Herball*. From the earliest times its long bean-pods have been eaten by man and lower animals; they were thought at one time to have supported John the Baptist in the desert—hence the names "locust beans" and "St. John's bread." In Sicily a spirit and a syrup are made from them.

During the Spanish civil war[3] it was observed that poor children, whose food consisted largely of these beans, did not get the diarrhœa which was prevalent among children of the rich. Moreover, children sometimes developed obstinate constipation after eating the beans. So research into the properties of the beans was instituted in Spain[3] and in Switzerland.[4] Soragni,[5] in Italy, has since treated 11 cases of diarrhœa in children with a preparation of locust beans made into a flour with starch and cocoa powder by Messrs. Nestlé under the name 'Arobon.' This contains fat 1%, protein 4·5%, carbohydrate 40%, "amido" 15%, mineral salts 3·5%, pectin 1·5%, cellulose 6%, lignin 23·5%, and water 5%: calorie value 250 per 100 g. The results of treatment were good, and the success has been attributed to the large content of lignin, whose properties resemble those of pectin. Neyroud[6] thinks that the flour adsorbs toxins and also helps to re-establish a normal bacterial flora in the gut. Scarzella[7] has used it to treat diarrhœa in 23 babies, aged 1–14 months, and has found that usually within 12 hours the colour of the fæces changes, and their reaction becomes acid instead of alkaline. He emphasises that locust-bean flour must be regarded as a medicine rather than a food.

"A COUPLE OF ASPIRINS"

FOR many years now aspirin has been the domestic panacea. Toxic reactions, including gastric hæmorrhage and anaphylactic phenomena, may be alarming but are fortunately very uncommon. A recent American report suggests, however, that the safety of aspirin for young children has been too readily assumed. Erganian, Forbes, and Case[8] have seen, within two years, 13 young patients with symptoms attributed to salicylate intoxication, mostly after aspirin had been given for a "cold." All showed a similar pattern of acid-base imbalance which the authors believe to be characteristic of this poisoning in the young. The clinical picture was of a severely toxic, febrile, apathetic, or even semi-comatose, infant, with increased, deep, and pauseless respiration, vomiting, and disinclination for food or drink. The patients were either very pale or cyanosed, and dehydration was pronounced. Spontaneous hæmorrhages in the skin and from the gastro-intestinal tract were seen in 2 cases. The urine contained albumin, casts, and ketone bodies. Treatment consisted in gastric lavage, subcutaneous glucose-saline, warmth, and oxygen; and to counteract the acidosis M/6 sodium r-lactate was injected in Ringer's solution. In all, except one infant of four and a half months who died from renal failure, the condition improved within two hours.

Erganian and her colleagues find that salicyl compounds in a dosage of about $^1/_2$ grain per lb. body-weight (in six divided doses) in the twenty-four hours tend to accumulate in the body; and they think that in infants who show no sign of renal failure, diarrhœa, diabetes, or severe infection the combination of hyperpnœa and listlessness with fever should suggest salicylate intoxication. The frequency of such poisoning in Britain cannot be estimated, but it might be well to adopt the American workers' proposal that aspirin should never be given to infants, and that it should be prescribed for young children only with caution and a watchful eye for signs of overdosage.

REGISTERS FOR 1947.—The *Medical Register* contains 76,292 names, being 1159 more than twelve months ago. During 1946 2237 names were added, and deaths totalled 1043. The number of temporary foreign registrations has increased by 101 to 3449.

The *Dentists Register* contains 15,266 names—156 fewer than twelve months ago.

for the mines must make use of physicists, physiologists, and engineers as well as doctors, to reduce dust, improve bad lighting, and restrict causes of accident to the unforeseen. All new miners should be examined on entry, and those working on the face should be examined at intervals, to ensure that only those fit for this work are employed on it, and that those who show early signs of pulmonary disease are removed from it.

Commenting on an article[3] on the care of the aged by Mr. Seebohm Rowntree, the editor of *Industrial Welfare* notes that the capacity for work and ability to learn has been shown to be much higher among the ageing than is usually assumed, and that their speed of work, reliability, and absence-rates compare very favourably with those of younger workers. Once physical power has declined they can hardly be used in heavy industries, of course, but he suggests that in the lighter trades—as the textile industry has proved—our labour force could be much augmented by allowing older men and women to continue in full or part time work.

PHYSICAL ANTHROPOLOGY

In the last decade or two the science of physical anthropology has enlarged its horizon, multiplied many times the number of its unofficial devotees, and transcended its name. The metamorphosis is largely due to these unofficial professionals, for there are only a handful of self-styled physical anthropologists, and in any case advances have mostly come from fields outside the old science. The development of the blood-group investigations was perhaps the beginning. With it came the promise of ever-increasing data on human genetics, and of a clarification of the old muddled problems of race classification and race origins. In America in the 1930's ambitious studies of child growth began; anthropometry has gradually become dynamic. Physiologists of all sorts, but especially those concerned with endocrinology and those interested in man's adaptation to artificial environments, began to contribute. Psychologists like William Sheldon in America and Cyril Burt in England revivified and extended the constitutional studies of the old Italian school of clinical anthropologists; their findings seemed, too, to hold the germ of yet more interesting investigations on the psychological correlates of physique and physiological function. Meanwhile, in the more familiar territory of palæoanthropology and comparative anatomy, material has been accumulating faster than ever before.

All this activity is well reported in a new American *Year Book of Physical Anthropology*, whose first number has belatedly come to hand. The year covered is 1945, and the book is a paper-bound collection of reprints of twenty-six articles. A particular effort has been made to gather contributions from journals off the anthropologist's beaten track, and none from the *American Journal of Physical Anthropology* is included. All, however, are in English, and we may hope that in future years French, Swiss, Scandinavian, South American, and Russian work will find a place. Nevertheless, most of the new—and old—interests of physical anthropologists are well represented, though there is little on growth or physique and nothing on human physiology.

A long article comes from Franz Weidenreich on fossil man in Java, with a welcome tabulation of all hominid fossils discovered there up to 1941. W. E. Le Gros Clark contributes two further papers on palæoanthropology. Adolph Schultz and William Strauss jun. are represented by a contribution on the number of vertebræ in the primates, which will long remain the most informative account of this subject; it gives a classification of primates and a considerable bibliography. Papers on functional anatomy are particularly plentiful, and include two by H. Haxton on joint structure and movement, one on the structure of the external nose, and another on variations in the form of the vertebral border of the scapula. No fewer than five articles are devoted to some aspect of tooth formation or evolution; but there is only one on human genetics—by L. H. Snyder and F. Blank on the inheritance of the shape of the sella turcica. Finally, an entire chapter of Alexander Wiener's *Blood Groups and Transfusion* is reprinted, with tables of racial distribution of the ABO and MN characters complete to 1943. It comes as something of a shock to find in this chapter only a few paragraphs on the Rh groups—so quickly has the subject developed—but a table of these up to 1945 is included in a further article by the same author.

This yearbook in short contains much information of interest to those who are not primarily anthropologists, as well as a useful conspectus for those who are.

VENEREAL DISEASE IN BRITISH WEST AFRICA

Smallpox, dysentery, cerebrospinal fever, plague, typhus, rabies, leprosy, yellow fever, malaria, blackwater fever, trypanosomiasis, bilharziasis, filariasis, infestations with intestinal worms, yaws, and dietary deficiencies are but a few of the special problems confronting the medical authorities responsible for the West African colonies, and somewhere in this long list have to be fitted tuberculosis and venereal diseases. The Colonial Medical Service is hopelessly understaffed for the job—in Nigeria, for example, there is only one doctor per 130,000 of population.

No-one who served with the Forces in that area can have failed to be impressed by the high incidence of venereal disease among the African troops, and, though the task of obtaining a substantial improvement may appear impossible, the problem is multiplying as long as nothing energetic is done. Judged by the published medical statistics of the four colonies the venereal disease situation would not appear to be so bad as for some of the other diseases listed. The annual medical report for 1943 shows that in the Gambia, for example, 1555 patients were treated in the hospitals and dispensaries for venereal disorders—a ratio of 7·77 per thousand of the population of 200,000. However, in the *African troops stationed there in 1944*, when the majority of sufferers were seen by a doctor, the ratio was 120 per thousand. In Sierra Leone, with a population of 1,770,000, in 1943 some 3880 of such patients were treated in the civil hospitals,[1] or 2·19 per thousand of the population, but in the Army the ratio in 1944 was as high as 279 per thousand. In the Gold Coast the annual report for 1943 reveals an even wider difference—11,903 civilian patients of the 3,790,000 population were treated, or 3·14 per thousand, while the Army figures reached the *staggering total of* 500 per thousand or 50% per annum. Of the $20^{1}/_{2}$ million in Nigeria, only 44,625 patients are reported as treated by the civilian authorities in 1943, a ratio of 2·17 per thousand. Comparable Army figures for 1944 are not available, but the estimated incidence of gonorrhœa alone in West African personnel was in the astronomical region of 625 per thousand. Thus, taking the four colonies together, in 1943 the civil authorities treated some 62,000 cases of venereal disease in a population of $26^{1}/_{4}$ million; *while in 1944 the Army* treated 27,800 such cases out of about 60,000 African troops.

It is evident from these figures that only a few drops are being pipetted from a vast cesspool, and it is to be hoped that future methods employed in tackling this problem will include not only better treatment for the small nucleus already secured but an imaginative scheme aimed at substantial portions of the whole. That there are regions of comparative freedom is shown in the difference in the numbers involved in the Gambia and, say, Nigeria. In 1938 Purcell[2] said he had treated over 5000 cases of yaws in the Northern Territories of the Gold Coast in a tribe where there was no gonorrhœa or clinical syphilis. Therefore even in the more infected and horticulturist, but to the many millions of individuals who can make their own substantial contribution to the food-supply if they are given good reason to do so. In producing many important items of food—potatoes, vegetables and fruit of many kinds, and poultry—the ordinary Englishman (especially when he has a five-day working week) is ready enough to play his part. But if he is to do so he must have the necessary incentive; we must put an end to the artificially low prices now prevailing for these things. If he can buy potatoes and eggs in the shops at the present subsidised price, the incentive to produce them for himself and for his neighbours rests wholly on his own actual shortage of them. Once increase the price of these things to a level corresponding to our need, and production everywhere will take a sharp upward turn. Our present policy discourages all effort except by the subsidised large-scale producer. Here is one way of reducing our imported-food bill to which we are turning a blind eye.

[2] Purcell, F. W. *W. Afr. med. J.* 1938, 7, 96.

It does not follow, however, that subsidies could be dispensed with. For if the prices paid to producers are allowed to find a natural level it will be necessary to use Government money to reduce the burden on consumers where it is worst borne.

PLANNING

The case here made for incentives first, and redistribution of the national income second, should not be confused with the cry for laissez-faire so often heard from some sections of the business community. It is not, indeed, a case for absolute priority for incentives over redistribution, but rather for logical sequence and orderly thinking. It is quite possible to arrange incentives aright, and at the same time to proceed with redistribution in the interests of social justice. What is dangerous, and what is at present hampering us, is failure to recognise the need for economic adjustments on a sufficiently drastic scale, and having done so to plan the redistribution in the light of these requirements. What the Government are trying to do is to settle the programme of redistribution on the basis of the old economy, the old scale of imports, and the old allocation of man-power and resources as between different occupations; and then to force the economy of the country into line. If the new Planning Chief is not given a real opportunity to assess the relative merits of the alternative methods whereby an underlying balance may be attained, he will prove but another cog in the machinery.

Measured in terms of man-power, only about $^1/_{15}$th of our resources is devoted to agriculture, and on the face of it the radical change in our import-export situation dictates a drastic revision of this ratio. If this $^1/_{15}$th were doubled or trebled, our livelihood would cease to depend on the success of the drive to double our exports—a success which under present conditions is at best problematical. Admittedly the difficulties standing in the way of so big a reallocation of labour are formidable. In particular, if we think that a big rise in agricultural prices and wages is the only means of drawing man-power back to the land, we must discover how it can be applied without causing a fresh all-round increase in the cost of living and an inflationary wage movement. These difficulties, however, are not insurmountable, and it is high time they were given more serious attention in official circles than they seem to have had so far.

Planning, it has been well said, is not a matter of superimposing some new authority: "it is much more a question of providing existing authorities with information sufficient to enable them to coördinate their work effectively and accurately." In the national sphere today it is up to the economists to provide the data needed to display the choices before us.

SHORTAGE OF NURSES

Hospital Doctors' Review

THE fevers group of the Society of Medical Officers of Health and the London and Home Counties branch of the Medical Superintendents' Society met in London on March 14, to discuss the nursing shortage. The following memorandum * embodies the meeting's discussion and conclusions.

CHARACTER AND INCIDENCE OF THE NURSING SHORTAGE

It has been stated that there are more nurses in the country today than ever before. This may be so, for nurses are now employed much more than formerly in attractive jobs outside hospitals—e.g., in public-health and school services, day nurseries, and factories. Furthermore, the shorter hours now worked in many hospitals necessitate an increase of some 10–12% in the number of nurses.

It is pre-eminently in the local-authority hospitals, the special hospitals, and the smaller voluntary hospitals that the acute shortage of nursing staff exists. Most of these have been compelled to close a considerable proportion of their beds because of it. London is particularly hard-hit: most of the local-authority general hospitals in London have had to close down about half their beds and the fever hospitals even more. This means daily refusal of admission to thousands of cases recommended to hospital. It also threatens, as far as the fever hospitals are concerned, the training of medical students and graduates.

It is said, on the other hand, that the great London voluntary hospitals with medical schools have no shortage of nurses, and have, indeed, waiting-lists. This is doubtless due partly to the inherent attractiveness of these hospitals. These discrepancies in staffing as between different kinds of hospitals have been greatly increased since the Rushcliffe scales of salary were introduced in 1943. The Rushcliffe policy of uniformity of salary-scales for all hospitals, regardless of their varying appeal to prospective nurses, is undoubtedly a major factor in the shortage which now threatens the existence of many local-authority and other hospitals.

FEMALE POPULATION CONCERNED

The Registrar-General has kindly supplied the following estimate for England and Wales of females aged 17 in the 25 years from 1922 to 1946 (figures given in thousands): 358, 356, 360, 367, 364, 357, 350, 346, 353, 354, 345, 314, 296, 263, 262, 399, 374, 357, 334, 324, 315, 309, 300, 291, and 291. Thus, the main average female population from which nursing recruits may be drawn dropped from 361,000 in the quinquennium 1922–26 to 301,200 in the quinquennium 1942–46—a decrease of 16% in 20 years. If we compare the earlier quinquennium with the 2-year period 1945–46, however, the drop is nearly 19%. Owing to the continued low birth-rate during the years 1930–45, the available population is unlikely to increase and is more likely to decrease during the next 15 years. We have, therefore, good reason to reckon that for the next few years the female population available as potential nursing recruits will be some 20% less than that available a quarter of a century ago.

ALTERNATIVE EMPLOYMENT

From this diminished female population, the proportion attracted to industry, to the Services, and to clerical and administrative work has increased as compared with that entering hospital nursing. The reasons usually advanced for this shift include the higher wages, shorter hours, advantages of home life or unrestricted private life, and the generally easier time enjoyed in those alternative occupations. On the other hand, the nurse's

THE NATIONAL SITUATION*

Social Objectives and Economic Necessities

FROM A CORRESPONDENT

It happens that since 1939 two of the most dramatic changes that have ever occurred in our economic life have taken place together.

First, the loss of our foreign assets has precipitated the need for a great alteration in our way of living: we no longer possess the income from foreign assets which for a century has enabled us to enjoy imports greatly in excess of our exports. Secondly, the country has taken a great step forward in its determination to put social welfare above the freedom of the old unrestricted industrial England.

Our present malaise is largely due to the combination of these two changes, and our failure to work out their implications.

Had the first change occurred by itself, the old corrective process of supply and demand would after its own fashion have provided a solution. There would, for example, have been a sharp rise in the prices of many things hitherto imported from abroad, and in due course a reallocation of our internal resources between one occupation and another. This would have been attended by high prices and high wages in some occupations, and by low prices, low wages, and unemployment in others. Though the social consequences would have been most uncomfortable, and the cost in human welfare very heavy, the economic machine would eventually have attained a new equilibrium.

Had the second change occurred by itself the picture would again have been different. The determination to put social welfare above industrial laissez-faire means primarily two things: (1) the setting of a brake on the old corrective machinery of supply and demand, and especially on its chief instrument, unemployment; and (2) redistribution of the national income to ensure a fair share of the necessities of life for all before superfluity for the few—a redistribution which has been attained partly by taxation, partly by rationing, and partly by food subsidies. These things—rather than the present drive for nationalisation and a "planned economy"—are the essential features of the drive for social justice on which all parties are at heart agreed.

Now had this programme had a fair field in which to operate—i.e., relatively stable economic conditions—a great social advance would almost certainly have been achieved at a moderate cost in economic efficiency. The refusal to use unemployment as a means of transferring labour from one industry to another is unimportant in relatively stable times; for other methods, such as discouraging entry into a particular industry, are sufficient to bring the desired results. Similarly, given relatively stable conditions, the redistribution of our national income by taxation, rationing, and food subsidies need not have unduly disturbed the economic machine.

The tragedy of our present plight is that these two trends are in absolute conflict. We have on the one hand an economic situation which urgently demands a reallocation of our resources, and on the other hand a social policy which not only abhors the old corrective mechanism but actually obscures the need for any adjustments at all. We cannot go on fumbling like this. If we are to retain the measures we have already taken for social betterment, and to go further on the same path, we must promptly devise some means of distinguishing more clearly between economic necessities and social objectives. Without this clear-cut distinction, the "planning" which is now our recipe represents no more than a groping towards a solution. Once the economic necessities stand out stark and clear we can consider how far their operation can be controlled in the interests of social welfare.

THE FOOD PROBLEM

The conflict between these two forces is nowhere more evident than in our handling of agriculture. Until 1939 we pursued a policy of importing food—to such an extent that half our import bill was in respect of food, and only about 40% of our requirements was produced at home. Today the import-export balance has undergone a radical change, and we cannot find enough foreign currency to pay for food imports on the old scale. But though we have granted the farmer fixed prices and thereby improved his prospects, we have not yet recognised the need to devote to home agriculture a far greater proportion of our resources.

The adjustment required can be grasped only if we remember that for over a century agriculture has been steadily drained of man-power, not only in numbers but in quality, since able and ambitious men have been steadily attracted into industry and commerce. In estimating what home agriculture is capable of providing, it is idle to use figures (like those of the white-paper recently published by the Government) which ignore the possibilities of a policy which would put this process into reverse. If we want to get more out of the land, the reward to the producer must be allowed to rise: it is insufficient to offer the farmer merely his cost of production plus a reasonable profit—there must be real monetary incentive on a grand scale until the needs of the community are met and a new equilibrium is attained. Under the old regime of supply and demand such a change would have occurred; and from the economic angle the necessity for it can be decisively demonstrated.

As things stand today the nutritional and social policies of the Government keep the price of food to the consumer under rigid control; and, despite the subsidies, the reward to the farmer is fixed by reference to cost of production. By obscuring the possibilities of a rapid rise in production of food, this policy has played into the hands of the export industries, to which we are told to look for the £300–400 million needed to balance our import-export account. These industries have been given priorities; the home market is subjected to rigid controls; and we have almost unwittingly embarked upon an attempt to draw a still greater proportion of our man-power into industry, with all the doubtful consequences that such a policy must entail if it succeeds. The Government have thus been led into all sorts of difficulties; they have on their hands a shortage of man-power for the basic and export industries, and no real means of correcting it; and a huge bill for stabilisation of the cost of living which reflects their attempt to continue to import food on the old scale and yet maintain prices to the consumer at a low level.

Standing in too close a proximity to the industrial and commercial life of the nation, the Government and their advisers assume that salvation is only to be found by a search for pre-war standards of living along the road that leads to enhanced industrialisation. If only our planners could be induced to step back a few paces and see the goal in perspective!

INCENTIVES

If we take things in the proper order, we must surely recognise the need for a steep rise in the incentives to the producer of home-grown food—a rise sufficient to draw into the field a larger proportion of our man-power and other resources. This applies not only to the farmer

Social Objectives and Economic Necessities

FROM A CORRESPONDENT

It happens that since 1939 two of the most dramatic changes that have ever occurred in our economic life have taken place together.

First, the loss of our foreign assets has precipitated the need for a great alteration in our way of living: we no longer possess the income from foreign assets which for a century has enabled us to enjoy imports greatly in excess of our exports. Secondly, the country has taken a great step forward in its determination to put social welfare above the freedom of the old unrestricted industrial England.

Our present malaise is largely due to the combination of these two changes, and our failure to work out their implications.

Had the first change occurred by itself, the old corrective process of supply and demand would after its own fashion have provided a solution. There would, for example, have been a sharp rise in the prices of many things hitherto imported from abroad, and in due course a reallocation of our internal resources between one occupation and another. This would have been attended by high prices and high wages in some occupations, and by low prices, low wages, and unemployment in others. Though the social consequences would have been most uncomfortable, and the cost in human welfare very heavy, the economic machine would eventually have attained a new equilibrium.

Had the second change occurred by itself the picture would again have been different. The determination to put social welfare above industrial laissez-faire means primarily two things: (1) the setting of a brake on the old corrective machinery of supply and demand, and especially on its chief instrument, unemployment; and (2) redistribution of the national income to ensure a fair share of the necessities of life for all before superfluity for the few—a redistribution which has been attained partly by taxation, partly by rationing, and partly by food subsidies. These things—rather than the present drive for nationalisation and a "planned economy"—are the essential features of the drive for social justice on which all parties are at heart agreed.

Now had this programme had a fair field in which to operate—i.e., relatively stable economic conditions—a great social advance would almost certainly have been achieved at a moderate cost in economic efficiency. The refusal to use unemployment as a means of transferring labour from one industry to another is unimportant in relatively stable times; for other methods, such as discouraging entry into a particular industry, are sufficient to bring the desired results. Similarly, given relatively stable conditions, the redistribution of our national income by taxation, rationing, and food subsidies need not have unduly disturbed the economic machine.

The tragedy of our present plight is that these two trends are in absolute conflict. We have on the one hand an economic situation which urgently demands a reallocation of our resources, and on the other hand a social policy which not only abhors the old corrective mechanism but actually obscures the need for any adjustments at all. We cannot go on fumbling like this. If we are to retain the measures we have already taken for social betterment, and to go further on the same path, we must promptly devise some means of distinguishing more clearly between economic necessities and social objectives. Without this clear-cut distinction, the "planning" which is now our recipe represents no more than a groping towards a solution. Once the economic necessities stand out stark and clear we can consider how far their operation can be controlled in the interests of social welfare.

THE FOOD PROBLEM

The conflict between these two forces is nowhere more evident than in our handling of agriculture. Until 1939 we pursued a policy of importing food—to such an extent that half our import bill was in respect of food, and only about 40% of our requirements was produced at home. Today the import-export balance has undergone a radical change, and we cannot find enough foreign currency to pay for food imports on the old scale. But though we have granted the farmer fixed prices and thereby improved his prospects, we have not yet recognised the need to devote to home agriculture a far greater proportion of our resources.

The adjustment required can be grasped only if we remember that for over a century agriculture has been steadily drained of man-power, not only in numbers but in quality, since able and ambitious men have been steadily attracted into industry and commerce. In estimating what home agriculture is capable of providing, it is idle to use figures (like those of the white-paper recently published by the Government) which ignore the possibilities of a policy which would put this process into reverse. If we want to get more out of the land, the reward to the producer must be allowed to rise: it is insufficient to offer the farmer merely his cost of production plus a reasonable profit—there must be real monetary incentive on a grand scale until the needs of the community are met and a new equilibrium is attained. Under the old regime of supply and demand such a change would have occurred; and from the economic angle the necessity for it can be decisively demonstrated.

As things stand today the nutritional and social policies of the Government keep the price of food to the consumer under rigid control; and, despite the subsidies, the reward to the farmer is fixed by reference to cost of production. By obscuring the possibilities of a rapid rise in production of food, this policy has played into the hands of the export industries, to which we are told to look for the £300–400 million needed to balance our import-export account. These industries have been given priorities; the home market is subjected to rigid controls; and we have almost unwittingly embarked upon an attempt to draw a still greater proportion of our man-power into industry, with all the doubtful consequences that such a policy must entail if it succeeds. The Government have thus been led into all sorts of difficulties; they have on their hands a shortage of man-power for the basic and export industries, and no real means of correcting it; and a huge bill for stabilisation of the cost of living which reflects their attempt to continue to import food on the old scale and yet maintain prices to the consumer at a low level.

Standing in too close a proximity to the industrial and commercial life of the nation, the Government and their advisers assume that salvation is only to be found by a search for pre-war standards of living along the road that leads to enhanced industrialisation. If only our planners could be induced to step back a few paces and see the goal in perspective!

---

* A previous article appeared on March 15

We consider that a shortened practical basic course of two years' duration should be undertaken by all nurses. This course should include three or four months' whole-time theoretical training in elementary physiology, hygiene, and dietetics; but the main emphasis should be on training in practical bed-side nursing. The examination should be entirely practical and should lead to qualification as "enrolled nurse." The practical training should be taken in any general *or special* hospital of suitable size. The status and remuneration attached to the grade "enrolled nurse" must be sufficient to satisfy the large numbers who would elect to remain in this grade.

For those who wished to rise to the rank of ward sister there should be one year's higher training in each of the following: medical nursing, surgical nursing, tuberculosis, fever nursing, mental nursing, and midwifery. The higher examination would be both theoretical and practical, leading to qualification as "State-registered nurse."

SPECIAL HOSPITALS

Much experience has shown that special hospitals cannot be staffed unless additional inducements are offered over and above those available to nurses in general hospitals. In fever, children's, tuberculosis, and mental hospitals student nurses and post-registration student nurses must be paid higher salaries than the corresponding grades in general hospitals. In addition, the full conditions of service recommended in the Rushcliffe report should be applied without delay to those special hospitals which have not yet put them into practice. This applies particularly to the 96-hour fortnight. Arrangements should be made for the nurse's private life to be removed from supervision by senior nursing officers. In mental hospitals there should be a longer preliminary training-school course in order to acclimatise new nurses to the treatment of patients. In those fever hospitals which are training-schools for medical students and graduates, specially attractive conditions of service are necessary in order to attract staff and so retain the teaching and other functions of these hospitals. Special hospitals of all types, provided they are of suitable size and have suitable equipment, should be able to provide adequate practical training for the basic course, leading to the qualification of "enrolled nurse."

MINIMUM AGES

The minimum age of enrolment as a nurse should be 20 years, and of registration 21 years.

CONSCRIPTION OR DIRECTION OF WOMEN TO NURSING

The plight of the hospitals must be faced: the closure of wards for lack of nursing staff is alarming, especially in London. The worst feature is that recruitment in many hospitals has virtually ceased. Within 12 months there will be a crisis unless some drastic improvement is made. Many of the hospitals, including large ones with training-schools for doctors and nurses, will be forced to close down or will be handed over to the National Health Service in a moribund state.

The facts set out above have driven some to consider that there is no ultimate solution to the problem except conscription of women, with direction of a certain number to nursing. Conscription might have to be considered seriously if all other methods of staffing hospitals failed. It would be much better, however, to attract staff voluntarily by improving the economic and other conditions of service of student nurses.

FOREIGN TRAINEES

The reduction in the total number of potential recruits, and the great demand for female labour in industry point strongly to the need for foreign immigrants sufficiently educated to train as nurses. There are, we believe, still large numbers of suitable young women on the Continent willing and anxious to come to Britain for such a purpose. Trained nurses, whether of foreign or British origin, are never likely to become a burden on the community through unemployment, but are likely to remain permanent assets.

PART-TIME HOSPITAL NURSES

The employment of part-time nurses, on the Gloucestershire model or otherwise, is to be encouraged. It is a particularly suitable method for nursing the chronic sick, since part-time nurses have other absorbing interests, and the time spent at the work is sufficient to interest and not to depress. The scope of part-time nursing in acute hospitals with training-schools, is however, limited, and the problem of staffing the hospitals as a whole cannot be greatly affected by schemes on these lines.

General Recommendations

1. Increased salaries (or training allowances) for student nurses in all approved hospitals where recruitment has seriously diminished.
2. Recognition of the principle of differential salary scales within limits for the grade of student nurse, in order to meet varying needs and conditions.
3. Recognition of the principle of "loading" for London in nurses' salary scales.
4. Establishment of pre-nursing training-schools under education authorities for selected school-girls *from the age of 15 years, with provision for small personal* maintenance grants.
5. A practical basic course of two years' training in approved general or special hospitals for all nurses, leading to qualification as "enrolled nurse," with *recognised professional status as a nurse and adequate* remuneration.
6. A higher qualification as "State-registered nurse," equivalent to the rank of ward sister. This would require advanced theoretical and special training.
7. Higher salaries for student nurses in all special hospitals as an urgent measure if these hospitals are to be preserved.
8. The minimum age for "enrolled nurse" to be 20 years.
9. Immediate arrangements for foreign immigrants to train as nurses.
10. Publicity for the advantages instead of the disadvantages of nursing as a profession, including more attractive advertising.

SOCIALIST MEDICAL ASSOCIATION

THE 17th annual general meeting of this association, held in London last Sunday, was attended by some 120 doctors and health-workers. Mr. SOMERVILLE HASTINGS, F.R.C.S., M.P., the president, said that the National Health Service Act provided a framework, sound in most (but not all) of its provisions, into which the detail had yet to be filled. Bad features were the retention of the pay-bed in hospitals, and the provision for part-time employment of doctors within the service. The association wished to see temporary health centres provided in all localities, and sites allocated for permanent centres.

The meeting adopted a resolution which welcomed the National Health Service as a positive contribution to the post-war reconstruction and pressed for staff committees in hospitals, elected by health-workers, which would take an active part in administration and policy. The association, it said, looked forward to the day when, following the inevitable reform of local government, the country's hospitals would be administered by local-government bodies. Health centres were pivotal to a satisfactory service.

The urgency of the nursing crisis was stressed in a resolution which emphasised the serious effects of the shortage of nurses, drawing special attention to the wastage of those who leave the profession before they qualify, and singling out institutional life as the main factor which deterred girls from becoming nurses and prevented completion of training. It called for the immediate transformation of nurses' homes into hostels run by lay wardens, immediate increases of pay for nurses, and the employment of part-time nurses on a nation-wide scale. An emergency resolution asked the Minister of Health not to approve any changes in the nursing curriculum without considering the views of organisations representing members of the nursing profession.

A resolution, passed unanimously, called on the Minister to resist any attempts to amend the provisions of the National Health Service Act dealing with abolition life has been represented for years in the press as one of "genteel poverty," hard domestic work (e.g., scrubbing floors), long hours, and semi-monastic severity. The facts, however, are that remuneration (except for student nurses) has been substantially increased, that ward orderlies are being recruited for the more menial tasks, that in most hospitals there is minimal interference by senior staff with the nurse's private life, and that any qualified nurse may live out. These facts, which are not yet widely known, should be publicised in every possible way. It is suggested that a propaganda film should be made by the Ministry of Health, and also that advertisements for nurses should be sited and framed so as to make a really popular appeal to prospective candidates.

RECRUITMENT OF NURSES

The shortage of nurses at present is one mainly of entrants to the profession—that is, of student nurses or other recruits.

Economic factors.—All our observations tend to indicate that, in London at least, the first and foremost reason for this shortage is the low salary offered to nurses in training under the Rushcliffe conditions of service. The Rushcliffe Committee rightly considered the nurse's prospects *after* training to be more important than an attractive salary during training. But the salary of trainees was fixed at figures which are now below the economic level and require subsidy from private sources, at least in London, if a reasonable standard of existence is to be maintained. A recent inquiry among the student nurses in a large London fever hospital as to the reasons for the virtual cessation of recruitment to the hospital revealed the following factors in their order of importance: (1) inability to live on their salary in London, (2) the unattractive uniform (mostly second-hand overalls), and (3) the erroneous belief amongst the public that student nurses had to do hard physical work and had poor off-duty time. The student nurses were pleasantly surprised to find that most of the hard work was done by ward orderlies and that the off-duty time was generous. They did not wish to live out; they enjoyed the communal life. They had no complaint as to restrictions on their private life, but in some cases resented "bullying" by certain ward sisters.

The Rushcliffe salary scales for student nurses, although slightly increased since 1943, have been rendered out of date by (1) the rising cost of living since 1943, and (2) the Hetherington scales for female domestic staff and the Mowbray scales for domestic staff, which have more recently come into force. The Mowbray scales recognise the principle of a "loading" of about 19% for London, which is not excessive considering the present high cost of maintaining even the smallest degree of social life in London. This principle should certainly be applied to nurses' remuneration.

WEEKLY WAGES OF CERTAIN RESIDENT STAFF *

	£	s.	d.
Student nurse, 1st year	1	1	2
" " 2nd year	1	5	0
" " 3rd year	1	8	0
Staff nurse (fever-trained) 1st year..	2	2	4
" " (general-trained) 1st year	2	6	2
Student nurse, general-trained (fevers)	1	14	7
Domestic assistant	2	17	0

* Plus board, lodging, uniform, and laundry.

A student nurse has to work and study for about seven years from the age of 17 or 18 before she attains to the remuneration of a maid aged 18 years. When superannuation, insurance, and the other necessary contributions are deducted, she has some 17*s.* or 18*s.* a week on which to clothe herself, travel, entertain herself on her day off, meet personal items of expenditure, buy textbooks, and pay examination fees.

It is clear that a higher salary (or training allowance) for student nurses is needed in those hospitals which cannot now attract recruits—e.g., fever, tuberculosis, mental, children's, and certain general hospitals. It should not be applied uniformly everywhere, for that would not cure the maldistribution of student nurses that now exists owing to the vast majority applying for admission to the great voluntary hospitals with medical schools. In order to preserve the balance, higher salaries (e.g., £100 plus emoluments) are needed in the less attractive hospitals; and in London, there should be a "loading" of 15–20% as in the Mowbray scales.

Social factors.—Formerly the sense or spirit of vocation was one of the most powerful motives in the recruitment of nurses. It inspired them to endure the discomforts of poverty, hard work, and long hours of duty. For this they earned the high respect of the community, and they also experienced a sense of satisfaction in their work which was largely its own reward. This unselfish spirit, however, came to be exploited by hospital authorities and the public; and this led gradually to the present emphasis on the economic factor. The economic motive cannot now be displaced, but it is still far from being the only motive. The sense of satisfaction derived from succouring helpless human beings will always remain the greatest attraction of nursing, and should ensure its professional status. This motive should be fostered in recruitment, especially among senior school-girls. In these times of economic stress, however, it is useless to rely upon the vocational motive, without at the same time offering reasonable monetary inducements.

TRAINING

The gap from 15 to 17½ years of age.—It is generally agreed that many potential recruits are lost because their interest in nursing is not sustained between the school-leaving age and the age of entry as a student nurse. Various efforts have been made to bridge this gap, but with little success. It is now clear that in order to obtain enough suitably educated nurses it will be necessary for education authorities to set up pre-nursing training-schools for suitable girls from the age of 15 years. A small maintenance grant would be necessary in most cases, especially in London. Subjects of instruction should include further general education, mothercraft, nursing methods, elementary anatomy, physiology, hygiene, dietetics, and domestic-science subjects—e.g., cooking, washing, and care of linen. During this course periodic visits might be made to day nurseries and hospitals, and in the last year of the course the girls might be fully employed in day and residential nurseries. An admirable scheme of this sort is actually in operation in the city of Dundee.

While this scheme would be expensive, it would be a substantial gain to education, it would materially aid the staffing of hospitals, and it would tend to eliminate wastage by better selection of recruits. Recruitment to these courses could be greatly stimulated through occasional lectures by selected speakers of wide general outlook to senior school-girls.

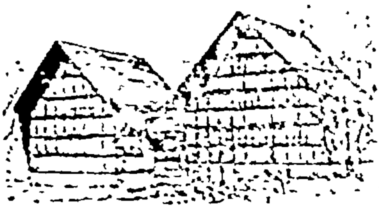
Short practical basic course.—The regulations of the General Nursing Council are too exclusively directed towards the enhancement of the professional status of the nurse and too little towards the production of sufficient practical nurses to care for the sick. The many women who are cut out for the practical work of nursing, but who are unable to master the theoretical teaching of the present syllabus, are not sufficiently encouraged to become nurses. They can, of course, train as an "assistant nurse," but the implied inferiority is not encouraging. This category is, moreover, at present largely made up of the early failures among student nurses, and is set to work almost exclusively at the less popular forms of nursing—e.g., the chronic sick.

The number of nurses required in the country is so large that it is wasteful and indeed impracticable to train them all, or even a high proportion of them, to undertake the most highly skilled work. The work of the hospitals demands large numbers who need no more than the basic skills of practical nursing, and only relatively few with an advanced theoretical training. But in order to give reasonable satisfaction to all concerned, the former group must be thoroughly well trained in practical bedside nursing, must be accorded the status of "nurse," and must have remuneration adequate to their status. We consider that the whole of the regulations of the General Nursing Council should be redesigned to this end, and that the Council should be endowed with responsibility for ensuring that its regulations for training are compatible with an adequate flow of recruits to the profession.

In England Now

A Running Commentary by Peripatetic Correspondents

I FIRST saw the children as they came running into their chalet for the midday meal, hungry and happy. It is easy to be sentimental about children, especially children who have come from concentration camps, from holes in the ground, from the garbage heaps of Europe—and all of them orphaned by the war. Certainly they do not spend much time on sentiment at the Pestalozzi children's village. They are anxious to get on with the work and to build more houses for new arrivals—houses without the slightest smell of an institution: no uniforms, no severe matrons, no barred windows or locked doors. Each nation has its own chalet, like the one illustrated here, where about 20 children from five to twelve years old are to live for ten to fifteen years. They are looked after by house-parents and treated as a large family.



Chalet at Trogen.

The village is at Trogen, in the north-east corner of Switzerland, five miles from Lake Constance. It is named after Johann Pestalozzi, the Swiss educationist, who died in 1827 at the age of 81. Disliking and distrusting the orphanages of his day, he collected as many down-and-out orphans as he could cope with, and brought them up as a family, regardless of their race or religion. It was in this spirit that W. R. Corti, a firm believer in Pestalozzi's ideals and the editor of an influential Swiss magazine, conceived the plan of the children's village. Switzerland was already giving holidays to war orphans, but he thought that three months' holiday was not enough. A child would soon forget this happy time when it returned to its own unfortunate country; better, he thought, to give a few children a really good home. So the scheme was started, and public subscriptions poured in. School-children of all ages gave up their holidays and went to help build the chalets; Swiss townsfolk sent practical gifts, and villages too poor to give money went out into the forests to fell trees, to be sold for the good cause.

Our arrival at the Austrian chalet was unexpected. We found the house-father helping one of the children to make a boat. Each chalet, set in a landscape of green hills and woods, has a playroom stocked with constructional toys and carpentry materials, bedrooms holding four or five children, and a modern washroom with showers. Each child has his own cupboard which he has carefully labelled with his Christian name only, because most of the children don't know their surnames. The young and energetic chief organiser proudly showed us houses already finished, and others in the building. But he knows that unless large sums of money can be raised the whole village will have to be written off as a failure.

We lunched in the French chalet with the children. They were happy members of a family; when the "parents" came in (young married people with a child of their own) the children rushed eagerly up to clutch at them and kiss them. During lunch the house-mother told the children that in the afternoon they were going to watch a tree being felled for them. This pleased and excited them, for they realised well enough it meant more help for the village.

In one room a piano—the only one the village has been able to afford so far—is the gathering point for a weekly sing-song, when all the different national songs are sung. The children like painting, and one twelve-year-old Polish boy was found in Warsaw scratching designs on the pavement. When he came to the village and was given all the painting materials he liked he worked every day at vivid but lurid scenes of street-fighting and battles. A freshly coloured landscape, just done, was the first work he had produced which had nothing to do with the war. Possessions are still a wonder to them: Johnny gets up each morning long before the rest to sit at his table in the school-room. When asked why, he said: "Because it is my own."

In Zurich we visited Herr Corti, who believes that now is the time to make the village an international affair. He wants to see other nations build such villages. France and Italy and a few other European countries are already interested. He even wants to build a house for the war-orphans of our country. But Switzerland alone has neither the money nor the scope to do all that must be done. Is it not time that we had an English village for children of all nations?

* * *

Her adenoids caressed the "well, I guess those were genu-ine Bedou-ine (both rhyming with wine) A (as in cake) rabs." We fled from her through the mountains to the Red Sea, to Suakin. One story about the origin of this old and now ruined port is that seven beautiful virgins, a present from the king of Abyssinia to the court of Egypt, once stopped the night there. When they finally arrived in Egypt they were all found to be pregnant, and the eunuch in charge was blamed. He escaped the king's wrath, however, because the girls claimed to have been visited during their night's halt by seven ginns who were the cause of their trouble. Pharaoh therefore packed them off back to the port, where they kept up their prolific reputations. On this theory the name Suakin comes from *Sawwa ginn*, which means "the ginn did it."

Having wandered through the old place, where some of the 1884 campaigns were fought, and the pilgrims now gather Mecca-bound, we went fishing. It was like using a bent pin in an overstocked aquarium. From the boat one could see through the crystal-clear water a million colours in nearly as many fish queueing for the old sardine. I. Walton would have been staggered by the experience.

* * *

We had a house-party the other day. Some jovial types coupled up the fire hose and inundated half the hospital. Then they threw a sofa and a bicycle out of a fourth-floor window. Next morning they felt terribly ill—especially when they heard that they had to pay for the damage. One would have thought that they had learnt their lesson. But no: they say: "By George, that was a wonderful party. Old so-and-so was absolutely stinking. Do you remember? . . ." They are looking for another excuse to blow off steam. Odd how educated men of above normal intelligence can behave when exhilarated en masse. Even when drunk they are lovable characters, but put them together when they are in that condition, and the whole appears to be very different from the sum of its parts.

* * *

Do many members of our profession look forward to Sunday mornings as much as I do? What joy to wake, not alas as one should in May to the cheerful singing of birds but to the monotonous sound of rain dripping on the lino outside, and to know that on this day at any rate I need not rush out wash-basin in hand to stay the flood before it cascades into the drawing-room below. "On Sunday the doctor breakfasts in bed." The family surges round me. The two children are ordered by their despairing mother to "get into Auntie's bed and keep quiet." My bath towel may be used to mop up the landing. My comb may be broken over the two-year-old's head. My secret store of handkerchiefs may vanish before my eyes, and the baby be potted in my bedroom as its Sunday treat. But all this is part of the joy of anticipation. Nine o'clock strikes. The gong is sounded and they are all gone. The elder child can vomit its breakfast. The cat can steal the baby's kipper, and the toast can be burnt to a cinder. I am away from it all. My housekeeper brings in my favourite dish. I relax and enjoy it. Truly a doctor's life has its moments. And if Sunday morning eight to nine is not one of the high spots nine to ten certainly is.

of the buying and selling of practices, the better distribution of doctors, and the inclusion of a basic salary in the payment of all doctors. Other resolutions called for the permanent provision of day-nurseries for children up to five years of age, and the abolition of charges for school meals. The nationalisation of all water undertakings was demanded, and legislation was urged for the abolition of patent medicines. The need for price-control for all essential foodstuffs was the subject of another emergency resolution, which was passed, and the last resolutions of the day expressed the need for a national economic plan, and for speedy demobilisation to overcome the man-power shortage.

The officers for 1947–48 will be: president, Mr. Somerville Hastings; vice-presidents, Dr. H. H. Joules and Dr. D. Stark Murray; hon. secretary, Dr. D. E. Bunbury; treasurer, Dr. L. T. Hilliard.

Medicine and the Law

Illegal Claim to Treat Disease

AT the Hampstead police-court on May 7 Jacques J. Harpman and the Institute of Endocrinology, Ltd., were fined £50 and £6 6s. costs each on six summonses relating to the publication of an advertisement.

Mr. A. C. Castle, prosecuting for the Pharmaceutical Society of Great Britain, reminded the court, that, under the Pharmacy and Medicines Act, 1941, it was an offence for anyone, even a doctor, to advertise an article which might be used to treat a number of diseases whereof cure was deemed either very difficult or hopeless; among such diseases, listed in section 8, were diabetes, infantile paralysis, and epilepsy. The defendant company, which was registered in 1931, formerly traded at Baker Street, London, W.1, and was now at 31, Heath Drive, N.W.3. Last October a Mr. John F. Armstrong wrote a letter to the institute asking for particulars of a certain treatment. He received in reply a list of ailments treated by the company, which included epilepsy, infantile paralysis, and diabetes. In the same envelope was a booklet, entitled "Hormone Therapy," bearing the name of the company, and that of Mr. Harpman, the managing director; this was apparently designed to impress on its readers the importance of the glands, in particular the pituitary, the thymus, and the pancreas. On the pituitary it said: "In short, the gland has a controlling influence in the growth of bones . . . such diseases as debility, impotence and epilepsy." On the pancreas: "The system needs sugar, but not too much . . . if it becomes flooded, we have a disease known as diabetes." On the thymus: "It is also used in other diseases of childhood such as infantile paralysis." In other parts of the booklet it was stated that "glands seldom work normally . . . let members of our Institute ascertain (the position) with their modern knowledge." Then in large block capitals: "Restore balance by our fresh hormone preparations."

Interviewed on Feb. 11 by an inspector of the Pharmaceutical Society, Mr. Harpman said he qualified as a doctor in South Africa in 1903 and was in practice till 1930. His age was 69 and he took his M.D. at La Plata University. In 1930 he founded the Institute of Endocrinology. The booklet was published in 1935 and he was not now distributing it. He had a few copies left and that was how it came to be sent to Mr. Armstrong.

Mr. Christmas Humphreys, defending, said that the institute had an enormous practice and had done a great deal of good work. There had never been a summons previously. Over 200,000 booklets had been distributed. "Then came the Act—a very remarkable document, because there are many thousands of people registered, and as many unregistered, who are required to heal their fellow-men of a variety of diseases mentioned in it. The Act discusses hopeless diseases; it says no person shall claim to treat the diseases mentioned. He may treat them, he may cure them, but he must not claim them. He must not advertise. The defendants have had to plead guilty to claiming to do something which they probably do do."

In spite of its frankness, this argument appears to have little effect. However that may be, the directors of the institute have now been made aware that further use of the booklet is definitely illegal.

Public Health

Decentralisation in London

THE London County Council has been considering how best to administer the local and domiciliary health services for which it will become responsible next year under the new Act. Some of these services are already administered by the council; others will be transferred to it from the metropolitan borough councils, still others are new duties. Last year the council resolved that the administration of these personal health services should be decentralised as far as possible and the plans drawn up by the L.C.C. general-purposes committee, after consultation with the borough councils, to give effect to this resolution were submitted to a meeting of the council on May 13.

The central administration of the services will be in the hands of a committee of whom 30 will be members of the L.C.C. and not less than 10 will be appointed from members of the City corporation (1) and borough councils (9). The remaining 6 will be coöpted. The day-to-day administration of the services will be entrusted to divisional health committees and for this purpose London has been divided into 9 divisions. The local committees, which will be appointed by the central committee, will have 12–23 members drawn from the borough councils included in the division and the L.C.C. in the ratio of 2 to 1. Each committee will also have 6 coopted members. Besides their responsibility for the detailed administration of the services the committees will report to the central committee on "local considerations," and they will be empowered to spend up to £500 "in any one case."

Smallpox

At Bilston, Staffs, the disease, originally thought to be variola minor, has proved to be variola major. As reported last week, a labourer, not included in the list of contacts, was taken ill on April 25 and removed to hospital on May 1, where he died the following day. Now his wife, vaccinated 64 years ago in infancy, and his son-in-law, aged 30 and unvaccinated, have developed the disease (vaccinated May 2; onsets May 7 and 8; rashes May 11; removed to hospital, May 11).

At Coseley, near Bilston, a woman, aged 78, confined to her house for several weeks past with bronchitis, developed high fever about May 1; the condition was diagnosed as pneumonia. A rash, first noticed on May 7, was thought to be due to chemotherapy, but by May 9 it had become semi-confluent; and on the same day the patient, now very ill, was removed to hospital. The original case at Bilston is said to have visited this patient's house "about a month ago."

A case of smallpox reported from Sheffield cannot at present be associated with a known source. An unvaccinated schoolboy, aged 11 and living in a tenement house, sickened on May 1 and developed a rash on May 4. The diagnosis was confirmed and the patient removed on May 10. Fortunately he had been confined to bed since the onset.

Infectious Disease in England and Wales

WEEK ENDED MAY 3

Notifications.—Smallpox, 1; scarlet fever, 873; whooping-cough, 2033; diphtheria, 186; paratyphoid, 1; typhoid, 1; measles (excluding rubella), 8142; pneumonia (primary or influenzal), 516; cerebrospinal fever, 52; poliomyelitis, 7; polioencephalitis, 3; encephalitis lethargica, 3; dysentery, 122; puerperal pyrexia, 122; ophthalmia neonatorum, 87. No case of cholera, plague, or typhus was notified during the week.

The case of smallpox was notified at Bilston, Staffs. Of the 122 cases of dysentery, 76 were notified in Lancashire (including 32 at Prestwich, 18 at St. Helens, 15 at Liverpool, and 6 at Whiston).

Deaths.—In 126 great towns there were no deaths from enteric fever, 2 (0) from scarlet fever, 2 (0) from diphtheria, 10 (0) from measles, 22 (3) from whooping-cough, 73 (6) from diarrhœa and enteritis under two years, and 12 (2) from influenza. The figures in parentheses are those for London itself.

The number of stillbirths notified during the week was 250 (corresponding to a rate of 26 per thousand total births), including 47 in London.

At the same time, I do not believe that the scientific attitude will lead to loss of liberty, but rather that understanding of the limitation of our ethical ideas will enable us the better to control our destiny, increase our freedom and tolerance, and further the highest aim of man—the increased happiness and well-being of our fellow-men.

London, W.1. RICHARD DOLL.

EXCHANGE VISITS WITH CONTINENTAL DOCTORS

SIR,—The World Friendship Association is anxious to hear from medical practitioners who are interested in the following plan: (1) to receive as a guest for fourteen days during August a medical practitioner from Denmark or Holland, and (2) to visit during the month of September a medical practitioner in Denmark or Holland and stay with him as his guest for fourteen days.

The cost of the return journey to Denmark from the port of embarkation will be 15 guineas; and for Holland the cost will be £9 10s. In addition a fee of 12*s.* 6*d.* is payable for membership of the association. The visits will normally be direct exchanges and are contingent upon hospitality being afforded here.

The World Friendship Association is an organisation which exists to foster understanding by arranging mutual visits. Hitherto its facilities have been available only to school-children and members of youth organisations; but it is now possible to extend them to adults.

Practitioners who are interested should write to Mr. G. A. Talbot, World Friendship Association, 29, Portman Square, London, W.1, marking the envelope "Medical Exchange."

London, W.C.2. RICHARD W. DURAND.

HOSPITAL ADMISSIONS

SIR,—May an assistant in general practice, who has had recent experience of the admission of patients to hospital from both ends of the telephone, make five comments on your article last week?

1. In the course of admitting nearly 60 patients to various hospitals in this area in the past year, I cannot recall any instance where the time between the hospital answering the telephone and the house-officer accepting or refusing the case was more than five minutes. Time has been wasted in some cases, but this was usually due to delay in getting the hospital number—i.e., the responsibility lies with the local telephone exchanges.

I should add here that most of my cases are sent to a large voluntary hospital in which the house-officers admit on a rota.

2. Any hospital with more than 200 beds which does not possess a buzzer, broadcasting, or other signalling device for summoning house-officers should be regarded as an anachronism. The value of such systems in speeding admissions is out of all proportion to the cost of instalment.

3. Much tiresome delay for the G.P. would be avoided if he would familiarise himself with the admission systems of the hospitals in his area. For example, in some hospitals time may be wasted in summoning the house-surgeon to admit a fractured femur, when the casualty officer is the man to do it. It may save time also if it is known that there are house-physicians for adult and for children's work, and house-surgeons for general work and for ear, nose, and throat.

4. The system by which one medical officer has responsibility for all admissions has the advantage of simplicity, and should be the rule in all small hospitals and in those without signalling devices. Where a signalling device has been installed, the house-officer rota system can be made to work as well, if not better, and the advantage for the G.P. is that he can talk to the man who is going to look after his patient, instead of passing messages through a go-between.

The only serious drawback to this system seems to be an occasional wastage of the patient's time on arrival at the hospital receiving-room before the appropriate house-officer arrives on the scene. I would suggest that all dangerously ill patients be sent direct to the wards, and that the housemen should take the G.P.'s word for the state of their patients.

5. Finally, the three hospitals in which I worked all used the admitting-ward system, but it was the duty of the house-officer to see that beds were available for emergencies during the take-in period. He would do this either by transferring convalescent cases to other wards or to convalescent homes, or else by reducing the admission of waiting-list cases.

Stokenchurch, Bucks. C. J. H. STAREY.

EMOTIONAL EFFECTS OF TRAUMA

SIR,—In my opinion Dr. Csillag (May 3) has underestimated the emotional effects of severe trauma. While I agree that amputations for grossly traumatised or severely infected limbs are rarely refused, it is difficult to accept the statement that "amputations are never followed by depression or suicidal tendencies." This may have been the case in battle casualties and other war injuries, but in civilian surgery the depression and often extreme melancholia which follows the loss of a limb is a factor with which every surgeon has to contend.

Probably the improvement which Dr. Csillag notes in the 2 cases reported was due to two factors: (i) the relief from pain afforded by removal of an infected or grossly traumatised limb, and (ii) general systemic improvement following the removal of a secondarily infected elbow-joint. The idea of giving a fretting and irritable child "something to cry about" can hardly be extended to traumatising a schizophrenic for the purpose of producing a shock.

Edinburgh. J. W. PERROTT.

PETHIDINE ADDICTION

SIR,—In his interesting paper of May 3, Dr. Polonio states that in pethidine addiction relapses are common, and then goes on to say that "none of our patients has relapsed hitherto." The general experience seems to be that relapse is inevitable unless patients accept a long period of psychotherapy, re-education, and rehabilitation.

As a rule addicts present themselves for treatment because it is socially or economically expedient to do so, or because they have infringed the law. The desire to be cured is mere lip-service to environmental pressure of one kind or another, and it rarely comes from a fundamental urge to reintegrate their personalities and reorientate themselves to a normal way of living. In other words, the desire for cure rarely arises spontaneously from within the addict. Moreover, as a group, drug-addicts are so unstable, and their lives become so complicated, that they seldom have the patience, or the means, needed for undertaking a complete cure.

I should be interested to hear how long Dr. Polonio's patients were under treatment before he considered them cured. It is comparatively easy to disintoxicate drug-addicts, but quite another matter to free them from the psychological craving which ultimately causes them to relapse.

London, W.1. ELLIS STUNGO.

SEASONAL CHANGES IN INSULIN REQUIREMENTS

SIR,—I should like to draw attention to a phenomenon which I have observed regularly each spring in some diabetic patients.

In a few of those who have been under my care for some time I have noticed that the insulin requirements change in the spring and again in the late autumn. In one case, which was otherwise well controlled, hypoglycæmic reactions suddenly became frequent in April and the insulin unitage had to be reduced; in the late autumn the dosage of insulin had to be increased to its previous level. Other cases of mine have shown similar though less dramatic variations. In none of these patients was there any increased bodily activity to account for the spring reactions; and likewise there were no complications to give rise to the hyperglycæmia and glycosuria in the autumn.

It seemed that the requirements of insulin in these people underwent a seasonal change, increasing in the winter and decreasing in the spring and summer. I should be interested to know if other practitioners have noticed similar changes.

Preston Hall Hospital, Maidstone. G. R. W. N. LUNTZ.

Letters to the Editor

ACADEMIC FREEDOM

SIR,—In the lecture you published on May 3, Professor Polanyi has, it seems to us, given a warning about the dangers in store for the younger scientific workers. His analysis of the freedom of the scientist is of great importance at a time when the whole conception of "freedom" has become the central theme of debate about the National Health Service.

There are two main fallacies in Professor Polanyi's arguments. Firstly, his two different concepts of freedom, "freedom from external constraint" and "liberation from personal ends by submission to impersonal obligations," are not, as he suggests, "near opposites"; at best they are statements of one aspect of the problem of freedom. Secondly, there is not in fact the hard-and-fast differentiation of scientists, or of science for that matter, into "pure" and "applied," of which he writes. Study of the history of science shows that there has never been any such thing as "research conducted for the advancement of knowledge" as distinct from applied science. Many scientists may think that they are just advancing "pure" science or knowledge, but in reality they are, to greater or lesser degree, helping to solve the problems of the society they live in. Newton is often quoted as an example of a "pure" scientist, but when one comes to examine his *Principia Mathematica* one finds that in this work he attempts to find the theoretical basis for the solution of the most important, practical, economic problems of his day. Thus, his work on ballistics arose from the social need to improve the accuracy of firearms, and his work on specific gravities from the requirements of the shipbuilding industry, &c. In other words, these sorts of problems were thrown up, as it were, by his particular economic and cultural period, and the measure of Newton's genius is the extent to which he helped to solve these problems and lay the foundations for the solution of many other, future problems. Similarly, the measure of Einstein's genius has been not the "beauties" or "internal logic" of his theories but the extent to which these theories solve practical problems. Conversely, the so-called applied science of the atomic bomb has helped to solve many "theoretical" problems of physics. In fact there is an indissoluble unity between the theoretical and applied aspects of science; "pure" science never has existed and never will.

The historical process of selection whereby certain scientific work emerges as important and other work (by far the greater proportion, incidentally) is forgotten, is not an haphazard one; it is essentially one by which theory is tested in practice—i.e., how far these theories fulfil the needs of society.

Freedom, whether scientific freedom or any other type, as Professor Polanyi verbally admits but implicitly denies, is not an absolute quality. As man's knowledge advances, as he is able to gain an increasing degree of control of his environment, so does he become more "free." Freedom consists in a mastery over ourselves and external nature founded upon the knowledge of the necessities of nature. In so far as man is able to find out the factors—economic, political, biological—which affect his actions, so, if he is able thereby to influence these factors and change nature, he has freedom. The extent of this freedom is determined by the accuracy of his knowledge and understanding, on the basis of which he can influence his environment.

If Professor Polanyi's general conclusions are applied to the present state of medicine it can be seen that they are not realistic. There is no sharp division between the "advancement of [medical] knowledge" and applied medicine. The two are interdependent. We doubt if other scientists would agree that there is a choice between "dedication to the advancement of a system of knowledge which requires freedom, or pursuit of applied science which involves subordination," but in the realm of medicine we are sure that such a distinction does not exist.

The "freedom" which we desire is not the spiritual abstraction of the Professor but the organisational facilities afforded by a planned service, to solve the very real medical problems which confront us. This does not mean a blind submission to "external authority" but active participation in formulating the plans which we ourselves will carry out.

London.

A. W. LIPMANN KESSEL
A. MCPHERSON.

SIR,—Professor Polanyi's lecture is valuable in showing that scientific and academic freedom is not an isolated phenomenon but is related to the totality of its social surroundings: it cannot be guaranteed merely by institutional forms, but blossoms only when the cultural and ideological traditions of the social milieu favour its growth. He rightly points out the difference between the anarchic individualist and the self-discipline of the individual scientist, with his multiple relations with his fellow-workers and with the whole body of traditional science.

But why should Professor Polanyi want to imprison the tradition and ideology of scientific freedom in the strait-jacket of philosophical idealism? History is against him. Plato in ancient Greece and Hegel in modern times have been the leading exponents of philosophical idealism and of the totalitarian State. The materialist tradition, from Epicurus and Lucretius to Voltaire and Marx, has favoured the free growth of science.

There is no necessity (except as a matter of personal faith or preference) to postulate a spiritual reality as the distinctive and unifying factor of science: what distinguishes the tradition of science from cabala, witchcraft, and astrology is the constant unification and testing of hypothesis in the light of verifiable facts. The revolutionary in science claims to be heard because he believes that his new hypothesis explains better than previous hypotheses a known range or a greater range of socially verifiable facts. Neither the discovery of sulphonamides nor that of their mode of action are discoveries of "hitherto hidden spiritual realities," but of material agents and of their mode of action in the presence of other material agents, in specific quantities and circumstances.

This constant testing of hypothesis with fact is the distinctive spiritual or moral tradition of science—not the search for spiritual objectives. This constant return to the world of facts and of social action also invalidates the too-sharp distinction drawn by Professor Polanyi between academic science and applied science. The two aspects of science interact on each other: each is necessary to the growth of the other; each languishes without the other. It is indeed a pity that Professor Polanyi feels himself compelled to believe that only those who hold certain unverifiable metaphysical assumptions are true and consistent champions of freedom.

London, W.1. E. MONTUSCHI.

SIR,—Professor Polanyi's article was extremely interesting—but how depressing! Is there really no other means of securing academic freedom than by demanding belief in essentially unconfirmable hypotheses? Science certainly requires acceptance of the reality of the external world, but beyond that some sort of experimental evidence is necessary before beliefs can be confidently held.

Professor Polanyi asks us to give reality to "transcendent ideas" with spiritual foundations, such as "absolute truth" and "absolute justice." Now, "transcendent" has different meanings in different systems of philosophy; but it is probably most often used in the Kantian sense of not realisable in experience, and I hesitate to acknowledge as transcendent, in this sense, more than is absolutely necessary.

Truth is the description of reality, and the conception of it must be relative to the observer and the existing sum of knowledge; the object of science is continually to make this description more general and more exact. Justice, which is a concept arising from the social relations of humanity, has been evolved for the protection of both the individual and the group; and no-one can hope to be just who does not realise the limitations of justice. History shows that in the name of transcendent ideas groups of men, such as religious sects, have carried out persecutions comparable to those of Hitler.

Parliament

ON THE FLOOR OF THE HOUSE

LATE night sittings and many divisions always bring discussion of the relative merits of American and British methods of voting. At Westminster M.P.s march through the lobbies, whereas members of the House of Representatives in Washington answer to a roll-call. But any one who has seen both methods has no doubt that the Westminster way, for all its seeming cumbrousness, is the quicker.

On Monday the third reading of the Transport Bill took place at 11 P.M. But after that we had a debate on physical education, and Mr. D. R. Hardman, parliamentary secretary to the Ministry of Education, was not very encouraging. The plans for a national college of physical education prepared by a committee under the late Lord Dawson of Penn proposed a building costing £350,000. But that cannot be carried out in this time of building and financial priorities. The National Fitness Council which was buried in 1939 remains buried, but the Minister said that this does not mean it cannot be resurrected.

Tuesday, Wednesday, and Thursday were taken up with the committee stage of the National Service Bill. The reduction of the period of service from 18 to 12 months—notified before Easter and immediately after the earlier debate—led to a spate of critical eloquence from Mr. Winston Churchill, but the Government carried their amendment after a division in which a bare handful voted against it; for the Opposition, while delighted at the chance to castigate the Government for their change of attitude, were not willing to lose the chance of passing a National Service measure in peace-time.

The medical and dental clause of the Bill, clause 9, was passed with a friendly comment by an Opposition medical M.P. and a brief explanation by the Minister of Labour in which he referred appreciatively to the work of the Medical Priority Committee. The medical side of the Services is as well organised as any and better than most, but there will be need to use our medical man-power economically for some time to come.

In the House of Lords Lord Woolton called attention to the danger of a serious shortage of food in this country, but disclaimed any intention of dividing the House or of unduly embarrassing the Government. A serious criticism made by Lord Woolton was that British farmers are not producing now as much as they did in the war. They could, he affirmed, give us an additional £150 millions worth of foodstuffs at present prices.

Lord Henderson's reply was reassuring but he was subjected to more interruption than is usual in the House of Lords. Perhaps there was a touch, or more than a touch, of politics in it. And, as Lord Woolton said, food and politics do not mix well. Lord Addison had to intervene at one point to say "this is not a question-and-answer entertainment; we are having a serious debate on food." Lord Henderson summed up by saying that Lord Woolton had fallen into an exaggerated condition of alarm and despondency, the situation was not really as bad as all that. But it seems likely that food facts will become missiles of controversy—and in the process a greater, even if often inaccurate, knowledge of food will be spread abroad.

MEDICUS, M.P.

FROM THE PRESS GALLERY

Peace-time Fare

The two-day debate in the Lords showed how pervasive food is, for it ranged with pertinence over agriculture, housing, man-power, foreign loans, and international trade. Lord WOOLTON opened the discussion on May 7 by saying that in his opinion we were in danger of a food crisis as serious as the fuel crisis during the next few months when the yield of the previous harvest would have been consumed. He begged the Government to be frank with the country. People wanted food, not "pep" talks, and he doubted whether our heavy workers were getting the right sort of food to enable them to give increased production. Lord Woolton quoted an article by Dr. Franklin Bicknell in the *Medical Press* (May 7) in which it was stated that: "England is dying of starvation. . . . Fat is what miners, farmers, fishermen, housewives all demand. Lack of fat is why we are all worn out."

Government buying was not giving us the goods, and people felt it would be better to have less politics and more knowledge in providing our food-supplies. If our dollars were dwindling why did we buy luxurious fruits? With our dollar shortage it was lamentable that British farmers are not producing as much as they did in the war. Lord Woolton surmised that the meat situation was serious. We were living beyond our income, and between January and April had used 150,000 tons of our stocks, and the loss of livestock in the bad winter had not yet been felt. Turning to bulk purchasing Lord Woolton affirmed that we were confusing the separate functions of government and catering, and trading and politics made bad companions. But he was, he added, concerned about supplies, not prices, and he begged the Government to secure food for the nation, never mind by what means.

Lord HENDERSON said the Government did not anticipate any disastrous increase of serious food shortage. There might be temporary cuts in some foods, but there would be increases in others. If there was no immediate prospect of a general removal of rationing control, there was no justification for alarmist prophecies of crises, and the prospects of a fair, though not a bumper, harvest were far better than anyone a month ago could have thought possible. We had, he admitted, been finding it difficult to maintain our supplies of wheat, and our present stocks made careful control necessary. But supplies from Canada now were coming forward freely and if this year's harvests were good it might be possible to abandon bread rationing. It was expected to increase the rations of animal feeding-stuffs in the coming year and to maintain the sugar, fats, and soap ration at their present level, but the meat ration might have to be reduced to the level ruling at this time last year. Potato supplies would be adequate to the demand, the supply of tea was being maintained with difficulty. Food was just as short now, he ended, as it was when Lord Woolton himself introduced many of the bulk purchase arrangements which he now criticised. We were not, Lord Henderson ended, living in a world of peace and plenty, but in a world that was only slowly recovering from the ravages and after-effects of war. But the Government would do their utmost to maintain and raise the food standards of the people within the limits imposed by the food shortage which continued to afflict a stricken world.

Lord BEVERIDGE recognised that today the food problem was harder than during the war, but he thought the Government did not have a clear grip of it. One of the best ways to save dollars was to increase our own agricultural produce, and that meant more men on the land and more houses for them. This Government, he also suggested, were too apt to be content with rationing; they were proud of it as a means of equality. They should aim not at supplies that will enable them to go on rationing for ever, but at supplies that will make it possible to abolish rationing.

Lord HAWKE felt that only by getting more than our fair share of food could we fulfil our part in the world recovery, yet the Government clung to the principle of international allocation. Lord SHEPHERD pointed out that in the past money had enabled us to buy food from countries such as Russia and India when the people were starving. Food was now, under UNO, the concern of an international authority which aimed not merely at regulating supplies but also at increasing production.

Opening the second day's debate, Earl DE LA WARR suggested that we could not deal with the crisis because we went on thinking of it as a crisis and not as a long-term change. We must and could produce more food at home and not regard agriculture as an emergency industry. The Earl of HUNTINGDON, parliamentary secretary to the Ministry of Agriculture, said that in the

of insanity was never raised at the trial and was never raised in the Court of Criminal appeal; and in view of the general disquiet about this case, will he assure the House that this is not a trial by doctors to supersede a trial by jury?—Mr. EDE: I am not bound in my consideration of the case by what has been submitted either to the lower court or to the Court of Criminal Appeal. I have to examine all the documents, and they are many and various, which come into my possession with regard to each case. If I have any doubt as to the mental stability of the person who has been sentenced to death it is my duty to order a medical inquiry. If that medical inquiry takes a certain course, the matter is then taken completely out of my hands.

Obituary

PHILIP ROSCOE WRIGLEY

F.R.C.S.

Philip Wrigley, who died, after a few days' illness, on May 2, will be remembered by many for his friendliness, even temper, and good sound surgery. To the first all who came into close contact with him can testify; of the second it may be told that he was one of the last to get upset, if ever he did get upset, by the trying climate of Mesopotamia where he served with the 33rd British general hospital in the 1914–18 war; and of the last, one can point out that in Manchester, when surgeons themselves needed operation, they called on Wrigley to do what was necessary.

Of an Oldham family he was educated at Manchester Grammar School, and he spent all his surgical life in Manchester's medical school and hospitals. He qualified in 1900 and obtained the F.R.C.S. five years later. At the Infirmary he was a popular and successful teacher, but he did not publish much, his main articles being descriptions of unusual abdominal cases from his extensive practice. He retired from active work about a year ago.

His brother, F. G. Wrigley, specialises in ear work in Manchester, and they are the only two brothers to have been on the staff of the Royal Infirmary together since the long-off days of the Halls, one of whom supported the Jacobite cause after the invasion of 1745.

Philip Wrigley leaves a widow, a son and a daughter.

E. B. L.

DR. S. MONCKTON COPEMAN

AT the memorial service to Dr. Copeman held at the Church of the Order of St. John of Jerusalem on May 7, Major-General R. J. Blackham said:

> "Wherever he went Copeman was an outstanding and welcome figure and his unfailing courtesy and consideration for others won him many friends in many sections of society. He loved not only humans but all forms of animal life, and as a member of the council of the Zoological Society he did much to improve the lot of the residents of the gardens he understood so well. Copeman's wide culture, travels in many lands, and retentive memory made him a delightful companion and nothing pleased him better than dispensing hospitality with a lavish hand. One of God's good men,
>
> 'He scarce had need to doff his pride or slough the dross
> of Earth—
> E'en as he trod that day to God so walked he from his birth,
> In simpleness and gentleness and honour and clean mirth.'"

MISS D. F. CLEPHAN

FOR more than 25 years, with the support of the Medical Research Council, Dorothy Clephan worked as illustrator with those engaged in radiological research and treatment at the Middlesex Hospital and the Marie Curie Hospital. She was responsible for the many coloured plates in the late Dr. Elizabeth Hurdon's *Cancer of the Uterus*. Equally successful in pen and ink, water-colour, photography, and plastic and other kinds of modelling, she was, in fact, a genius with her hands. Services such as hers are best appreciated by those who depend upon this kind of help to illustrate their problems when committing themselves to print. She was a gifted singer, and a delightful sense of humour rounded off her essentially gentle nature. She died on April 18.

S. R.

Appointments

BRASH, DAVID, M.B. Glasg., D.M.R.: radiologist, Bolton Royal Infirmary.

BULLOUGH, A. S., M.B. Manc., F.R.C.S.: surgeon, Hope Hospital, Salford.

CAMPBELL, EDWARD, M.B. Edin., D.P.H.: asst. venereologist, West Riding, Yorks.

CARRAGHER, A. E. P., M.B. N.U.I., D.P.H.: pathologist, Warrington Infirmary and Warrington municipal hospitals.

DAVIES, J. H. T., M.B. Camb.: dermatologist, Rochdale Infirmary.

DOBBS, R. H., M.D. Camb., F.R.C.P.: physician i.c. department of diseases of children, Southend-on-Sea General Hospital.

MCDOWELL, L. A., M.B. Belf., D.P.H.: deputy M.O.H., asst. school M.O., and asst. tuberculosis officer, Burton-upon-Trent.

MACPHERSON, IAN, M.D. Leeds, M.R.C.P.: consultant physician, St. James's Hospital, Leeds

NEWBOLD, J. C., M.B. Camb., F.R.C.S., M.R.C.O.G.: surgical registrar and obstetrical tutor, Jessop Hospital for Women, Sheffield.

SAVAGE, JOHN, M.B. Glasg.: dermatologist, Doncaster Royal Infirmary and Worksop Victoria Hospital.

SCHOFIELD, J. E., M.B. Manc.: anæsthetic registrar, Manchester Royal Infirmary.

SEVITT, SIMON, M.SC., M.D. Dubl., M.R.C.P.I., D.P.H.: asst. surgeon, Birmingham Accident Hospital.

SIMON, GEORGE, M.D. Camb., D.M.R.E.: asst. director, radiological dept., Hospital for Consumption and Diseases of the Chest, Brompton.

SINCLAIR, W. W., M.B. Glasg., D.P.H.: asst. county M.O., and M.O.H. for area 5, Norfolk.

WILSON, J. D., F.R.C.S.E.: deputy medical superintendent, Lord Mayor Treloar Cripples' Hospital and College, Alton and Hayling Island, Hants.

Middlesex Hospital, London:

BLOOM, ROSS, M.B. Wales, M.B. Lond., F.R.C.S.: fracture and orthopædic registrar.

SELLORS, T. HOLMES, D.M. Oxfd, F.R.C.S.: thoracic surgeon.

St. Mary's Hospital, London:

GIDEON, D. S., M.R.C.S.: specialist, ear, nose, and throat dept., St. Mary's Hospital and Princess Louise Kensington Hospital for Children.

LEIGH, A. G., M.D. Lpool, F.R.C.S.: asst. ophthalmic surgeon, St. Mary's Hospital, and ophthalmic surgeon, Paddington Green Children's Hospital and Princess Louise Kensington Hospital for Children.

MATHESON, W. J., M.B. Edin., D.C.H.: joint pædiatric registrar, St. Mary's Hospital and Princess Louise Kensington Hospital for Children.

ROBIN, I. G., M.B. Camb., F.R.C.S.: asst. surgeon for diseases of ear, nose, and throat, St. Mary's Hospital and Princess Louise Kensington Hospital for Children.

St. George's Hospital, London:

CHALMERS, J. N. M., M.D. Glasg., D.P.H.: asst. pathologist (clinical pathology).

MARTIN, N. H., B.M. Oxfd, M.R.C.P., F.R.I.C.: chemical pathologist.

Birmingham United Hospital:

Asst. radiologists in diagnostic X-ray dept..

BISHOP, J. C., M.C., M.B. Birm.

SMITH, O. E., M.B. Birm.

St. Peter's Hospital, Chertsey:

BAYNES, T. L. S., M.D. Lond., F.R.C.S.: gynæcologist.

ETHERIDGE, F. G., B.M. Oxfd, D.A.: anæsthetist.

GILLESPIE, H. W., M.D. Tübingen, L.R.C.P.E., D.M.R.: radiologist.

GOADBY, H. K., M.D. Camb., F.R.C.P.: physician.

MIMPRISS, T. W., M.S. Lond., F.R.C.S.: surgeon.

County Borough of Blackpool:

Asst. school M.O..

WARD, G. W., M.B. Manc.

WRIGHT, J. M. L., L.R.C.P.E., D.P.H.

Manchester Public-health Department:

CHADWICK, T. H., M.B. Manc., D.A.: consultant anæsthetist, Withington Hospital.

GOLDBERG, H. M., M.B. Lond., F.R.C.S. consultant surgeon. Booth Hall Hospital.

GRIFFITHS, D. L., M.B. Manc., F.R.C.S.: consultant orthopædic surgeon, Crumpsall Hospital.

HAXTON, H. A., M.B. St. And., F.R.C.S.: consultant surgeon, Crumpsall Hospital.

PARKINSON, J. S., M.B. Manc., M.R.C.P., D.P.H.: consultant physician, Withington Hospital.

ROBINSON, B. P., M.B. Manc., F.R.C.S.: consultant ear, nose, and throat surgeon, Booth Hall Hospital and Crumpsall Hospital.

SAVATARD, JUDITH, M.B. Lond.: consultant dermatologist, Withington Hospital.

SMITH, S. B., M.R.C.S., D.O.M.S.: consultant ophthalmologist, Booth Hall Hospital and Crumpsall Hospital.

SMITH, G. G. E., M.D. Manc., M.R.C.P.: consultant physician, Crumpsall Hospital.

WERTHEIM, LEOPOLD, M.R.C.S.: consultant dermatologist, Crumpsall Hospital.

Northants Maternity and Child Health Services:

Scientific Film Congress

A congress is to be held in Paris at the beginning of October to consider the draft constitution of an international film organisation which has been prepared by the British and French organisations. Further information may be had from the Scientific Film Association, 34, Soho Square, London, W.1.

University College of Nigeria

Mr. Kenneth Mellanby, D.SC., reader in medical entomology in the University of London at the School of Hygiene and Tropical Medicine, has been appointed principal-designate of the university college which is to be set up in Nigeria. Dr. Mellanby was appointed O.B.E. in 1945 for his services in connexion with the preservation of the health of our troops in South-East Asia.

Empire Rheumatism Council

The council will hold a week-end course on June 13, 14, and 15 at the Apothecaries Hall, Black Friars' Lane, London, E.C.4. The speakers will include Sir Adolphe Abrahams, Dr. Ernest Fletcher, Dr. R. E. Bonham-Carter, Dr. G. D. Kersley, Dr. George Graham, Dr. W. S. C. Copeman, Dr. Oswald Savage, Dr. F. S. Cooksey, and Mr. W. D. Coltart. Further particulars may be had from the secretary of the council, Tavistock House North, W.C.1.

New York Academy of Medicine

At the centennial convocation held on April 24 the following were elected to the membership of the academy as honorary fellows: Sir John Fraser, Dr. Gordon Holmes, F.R.S., Sir Wilson Jameson, Sir John Boyd Orr, F.R.S., and Prof. John Ryle. The following were elected as corresponding fellows: Prof. H. R. Dean, Prof. N. Hamilton Fairley, F.R.S., Sir Alexander Fleming, F.R.S., Sir Howard Florey, F.R.S., Prof. James Mackintosh, and Sir Lionel Whitby.

Society of Apothecaries of London

On May 8 the honorary freedom was conferred on Sir Stanley Hewett, and the mastery of midwifery, honoris causa, on Sir Allen Daley, Sir Eardley Holland, and Sir William Fletcher Shaw. Dr. Thackray Parsons, the master, said that the society, which had brought women into the medical profession by giving its licence to Elizabeth Garrett Anderson, is this year to admit women to its freedom. Claiming that medical education in England owes more to the society than to any other body, he described its influence on the provincial medical schools, almost all of which began by framing their courses of instruction to satisfy the requirements of its examining committee, and spoke particularly of its interest in midwifery, and the relations of midwifery to pædiatrics and to social medicine. Sir Stanley Hewett, in receiving the freedom, said that as surgeon-apothecary to H.M. the King for nearly 40 years he felt he had served his apprenticeship. Dr. J. P. Hedley, a past master of the society, introduced the new masters of midwifery, each of whom returned thanks for the honour.

R.A.M.C. War Memorial Fund

Launching a public appeal in London last week, Sir Alexander Hood, president of this fund, said that over £8000 had already been raised among personnel of the R.A.M.C. and the Emergency Medical Service. Further results could be achieved only through press publicity since the R.A.M.C., scattered throughout this country and over the world, had no territorial background; the Corps' essentially humanitarian work justified extension of the appeal to a wider public. Proceeds, said General Hood, were to be spent, not on a memorial in wood or stone but on the welfare of those who suffered during the war or of their dependants. Help would be substantial, so that in six or seven years the fund would cease; and "welfare" would be widely interpreted to include monetary grants and assistance—for example, in training for civil technical qualifications, in buying equipment, and in the education of children. After the 1914–18 war the corresponding fund totalled about £20,000; and it was hoped that this sum would be bettered. Subscriptions should be addressed to the hon. treasurer, c/o Glyn, Mills & Co., 22, Whitehall, London, S.W.1.

Return to Practice

The Central Medical War Committee announces that Dr. M. P. Leahy has resumed civilian practice at 30, Harley Street, London, W.1 (Langham 4012).

Diary of the Week

MAY 18 TO 24

Monday, 19th

ROYAL COLLEGE OF SURGEONS, Lincoln's Inn Fields, W.C.2
5 P.M. Mr. Norman Capener: Reconstructive Operations in Chronic Arthritis.
ROYAL SOCIETY OF MEDICINE, 1, Wimpole Street, W.1
5.30 P.M. *Odontology.* Sir Frank Colyer: Roman-British Burials.

Tuesday, 20th

ROYAL COLLEGE OF PHYSICIANS, Pall Mall East, S.W.1
5 P.M. Prof. R. E. Lane: Care of the Lead Worker (Milroy lecture).
ROYAL COLLEGE OF SURGEONS
5 P.M. Sir Thomas Fairbank: Developmental Affections of Bone.
LONDON SCHOOL OF DERMATOLOGY, 5, Lisle Street, W.C.2
5 P.M. Dr. R. T. Brain: Electrotherapeutics.
EUGENICS SOCIETY
5.30 P.M. (Burlington House, Piccadilly, W.1.) Mr. H. J. Eysenck, PH.D.: Measurement of Socially Valuable Qualities.

Wednesday, 21st

ROYAL COLLEGE OF SURGEONS
5 P.M. Mr. George Perkins: Lesion of the Epiphyses.
ROYAL SOCIETY OF MEDICINE
5 P.M. *Endocrinology.* Prof. F. G. Young, D.SC., Dr. R. D. Lawrence: New Aspects of Insulin Action.
LONDON SCHOOL OF DERMATOLOGY
5 P.M. Dr. C. W. McKenny: Technique of X-ray Treatment (part I).

Thursday, 22nd

ROYAL COLLEGE OF PHYSICIANS
5 P.M. Prof. R. E. Lane: Care of the Lead Worker (Milroy lecture).
ROYAL COLLEGE OF SURGEONS
5 P.M. Prof. Lambert Rogers: Ligature of Arteries (Arris and Gale lecture).
6.15 P.M. Mr. H. A. Brittain: Operative Treatment of Tuberculous Disease in the Larger Joints.
UNIVERSITY OF DUBLIN
5 P.M. (Dixon Hall.) Prof. B. R. Samuels: Sympathetic Ophthalmia (Montgomery lecture).
EDINBURGH POST-GRADUATE COURSES
4.30 P.M. (Royal Infirmary.) Mr. Donald Douglas: Surgery of Hydatid Disease.
CHADWICK LECTURE
3 P.M. (Cheltenham Town Hall.) Sir Arthur MacNalty: Advances in Preventive Medicine during the War of 1939–45.

Friday, 23rd

ROYAL COLLEGE OF SURGEONS
5 P.M. Mr. H. Osmond Clarke: Structural Deformities of the Spine.
ROYAL SOCIETY OF MEDICINE
3 P.M. *Epidemiology and State Medicine.* Dr. H. J. Parish: Future of Preventive Inoculations.
5 P.M. *Pædiatrics.* Dr. L. K. Diamond: Erythroblastosis.

Births, Marriages, and Deaths

BIRTHS

BLOMFIELD.—On May 9, at Sheffield, the wife of Mr. G. W. Blomfield, F.R.C.S.—a daughter.

COWPER.—On May 6, at Kingsbridge, S. Devon, the wife of Dr. W. H. Cowper—a daughter.

DAY.—On May 6, in London, the wife of Dr. F. M. Day—a daughter.

FYSH.—On May 7, at Roffey Park, Horsham, the wife of Dr. Christopher Fysh—a son.

HUNT.—On May 4, in London, the wife of Dr. John Hunt—twin sons.

LAMBLEY.—On May 6, at Northampton, the wife of Mr. D. G. Lambley, F.R.C.S.—a son.

LOW.—On May 3, the wife of Dr. M. G. Low—a daughter.

MASSON.—On May 2, in London, the wife of Dr. H. F. Masson—a son.

O'BRIEN.—On May 2, the wife of Dr. Brendan O'Brien—a son.

SMITH.—On April 11, in Ipswich, the wife of Dr. L. E. Smith—a son.

WOODS.—On May 5, in London, the wife of Lieut.-Colonel T. Woods, R.A.M.C.—a daughter.

MARRIAGES

DAVIS—LOESER.—On May 7, in London, Albert Davis, F.R.C.S., to Renate Marie Loeser, M.R.C.S.

MACARTHUR—PARTON.—On May 3, at Epsom, Angus MacLeod Macarthur, M.B., to Hilary Claire Parton, M.B.

POLLITT—ATTWOOD.—On April 30, at Stafford, P. G. H. T. Pollitt, M.B., to Gwendoline Attwood.

WILKINSON—EXELL.—On May 7, at Kensington, Ronald S. Wilkinson, B.M., to Thelma M. Exell.

DEATHS

ALCOCK.—On May 2, at Burslem, Staffs, Samuel King Alcock, M.D. Lond., J.P., aged 84.

CAZALET.—On May 10, at Bexhill-on-Sea, Grenville William Cazalet, M.R.C.S., aged 87.

CRAWFORD.—On May 4, at Martinstown, Dorset, James Muir Crawford, O.B.E., M.D. Edin., lieut.-colonel I.M.S. (retired), aged 80.

LOWSLEY.—On May 8, at Bradninch, Devon, Montagu Marmion Lowsley, D.S.O., M.R.C.S., lieut.-colonel R.A.M.C.

MILLER.—On May 2, at Blackheath Park, London, John Wilson Miller, M.B. Glasg., D.P.H.

WRIGLEY.—On May 2, at Swettenham, near Congleton, Philip Roscoe Wrigley, F.R.C.S.

STORIES OF ENDOCRINE RESEARCH*

E. C. DODDS
M.V.O., M.D., D.Sc. Lond., F.R.C.P., F.R.S.
COURTAULD PROFESSOR OF BIOCHEMISTRY IN THE UNIVERSITY OF LONDON
From the Courtauld Institute of Biochemistry, Middlesex Hospital, London

ENDOCRINE research, like all other types of research, can be conducted in various ways—in fact, we can use the investigations of the internal secretions as a model in the consideration of the whole question of the methods of research in general. The first I may perhaps call the Addisonian or even the Guy's method. No finer examples could be taken than the study of the two diseases in which Guy's men played such prominent parts in their elucidation: Addison's disease and myxœdema.

Thomas Addison (fig. 1) was born at Long Benton, Northumberland, in 1793, was educated at Newcastle, and took his degree in Edinburgh in 1815. He then came to London, where he was first of all house-surgeon to the Lock Hospital and then assistant to Dr. Bateman, a well-known skin specialist, at Snow Hill. He first went to Guy's in 1824 as assistant physician, and his selection for the appointment was largely due to the influence of the treasurer, Benjamin Harrison. He remained on the staff of Guy's until just before his death in 1860.

Accounts of him written by those who knew him personally all show him as an extremely forceful personality, with unrivalled powers of observation and an untiring persistence in searching out the hidden causes of disease. Wilks and Bettany (1892) say:

> "For many years he was the leading light of Guy's so that every Guy's man during the 30 or 40 years of his teaching was a disciple of Addison. . . . He was dogmatic in his teaching and thus the pupils accepted as pure gospel every word which flowed from his lips. The force of his words was enhanced by his mode of delivery and by the presence of the man himself. . . . His penetrating glance seemed to look through you and his whole demeanour was that of a leader of men enhanced by his somewhat marked attitude. . . . As a teacher, it is difficult to conceive a better. . . . The clinical lectures were most excellent, as he never failed to thoroughly unfold the case which he was discussing. . . . His examination of the patient was of the most complete character; possessing unusually perceptive powers, being shrewd and sagacious beyond the average of men, the patient before him was scanned with a penetrating glance from which few diseases could escape detection. He never reasoned from a half-discovered fact, but would remain at the bedside with a dogged determination to trace out the disease to its very source for a period which constantly wearied the class and his attendant friends. . . ."

Fig. 1—Thomas Addison (1793–1860).

Almost the same words are used by the writer of the obituary notice in the *Medical Times and Gazette* (1860).

Addison in 1849 and 1855 described several cases of lassitude, pigmentation of the skin, loss of weight, and death. The findings at necropsy invariably showed bilateral destruction of the suprarenal glands, to which Addison attributed the condition, suggesting that they mainly influenced the red blood-cells.

Dr. Trousseau, of Paris, first gave the name "Addison's disease" to the symptoms which Addison had described. Brown-Séquard (1856, 1858) showed that these symptoms could be reproduced in animals by removal of the suprarenal glands. Swingle and Pfiffner (1931) extracted from the cortex a substance which would maintain life in adrenalectomised animals and was sufficiently pure not to cause abscesses at the site of injection. Methods of extraction have since been improved, and the substance has also been produced by a sterol-degradation process (see below). By the administration of cortical hormone, patients with Addison's disease can now be kept in reasonable health over long periods.

MYXŒDEMA

Still another example of the Addisonian or Guy's technique is the research leading to the discovery of thyroxin. The first description of the condition now known as myxœdema was given by Sir William Gull (1873). Gull (fig. 2) was born at Colchester in 1816, and he also owed his entry to Guy's to Benjamin Harrison, who arranged for him to be entered as a student. Like Addison, Gull was distinguished for his powers of observation and diagnosis; and, like Addison, he held the view that to find out the cause of a disease was equally, if not more, important than to prescribe for it. The writer of the obituary notice in the *Guy's Hospital Reports* (1890) says:

> "He was never tired of exposing the absurdity of much of the traditional polypharmacy. He would show how much harm may be done by the vigorous treating of half-understood diseases and he once said that if every drug in the world were abolished, a physician would still be a useful member of society."

Fig. 2—Sir William Gull (1816–1890).

He was opposed to the granting of medical diplomas by the Society of Apothecaries once the Conjoint Board was established and said in this connexion:

> "The road to medical education is through the Hunterian museum and not through an apothecary's shop."

He was noted for his rather caustic wit, and his remark "Savages explain, science investigates," his description of a neurotic woman as "Mrs. A. multiplied by four," and so forth, are often quoted. Another obituary notice (*Lancet* 1890) remarks:

> "He had not exactly a vein of pure humour; for his humour was generally critical and sometimes sarcastic; and he would speak of the whims and fancies of men in terms of material pathology with a cheery satire quite inimitable, and yet with a depth of sympathy and a force pathetic and startling."

In 1873 Gull described "a cretinoid state supervening in adult life in women." He showed that the symptoms in these cases were very similar to those seen in cretins:

> "And that it is allied to the cretin state would appear from the form of the features, the changes in the lips and tongue, the character of the hands, the alteration in the conditions of locomotion and the peculiarities, though slight, of the mental state."

Ord (1878), who reported several cases of the same condition, which he termed "myxœdema," noted that:

> "You will find little or no trace of a thyroid body and a decided resilient fulness on both sides of the neck above the clavicles. . . . In the fatal case examined by me, the thyroid was reduced to about a fourth of its natural size. . . ."

---

* Addison lecture delivered at Guy's Hospital on Dec. 2, 1946.

Kocher (1889), reporting the results of 250 thyroidectomies, commented on the danger of myxœdema supervening as the result of complete removal of the thyroid gland, and he referred to this again in 1895.

Murray (1891) reported the successful treatment of a case of myxœdema with an extract of sheep's thyroid. He described the condition of the patient before treatment, gave details of a method for preparing a suitable extract, and reported the vast improvement in the patient when seen after three months' treatment.

The active substance, thyroxine, was first isolated in crystalline form by Kendall (1915). Harington (1926) proved its chemical constitution, and he and Barger (1927) synthesised it.

DIABETES

Sometimes this method hangs fire very seriously, and a typical example is diabetes. We have the disease described accurately by Hippocrates, though he did not know there was sugar in the urine. This was discovered in the seventeenth century by Thomas Willis (fig. 3), who was appointed Sedleian professor of natural philosophy at Oxford in 1660. He moved to London in 1666 and acquired the largest fashionable practice of his day. He gave the most complete and accurate account of the nervous system which had so far appeared, and gave descriptions of myasthenia gravis, puerperal fever, and epidemic typhoid. In his essay on diabetes, a translation of which was published in 1681, Willis says:

> "But that as many authors affirm the drink to be little or nothing changed is very far from truth, because the urine in all (that I have known who hath hapned to have it, and I believe it to be so in all) very much differing both from the drink taken in, and also from any Humour that is wont to be begot in our Body, was wonderfully sweet and as it were, imbued with Hony or Sugar."

Despite the most careful clinical studies, no progress was made until a chance observation of von Mering and Minkowski (1889) showed that the pancreas was connected with diabetes. Von Mering was interested in protein digestion and wondered what would happen if one removed the pancreas and therefore the source of trypsin. He and his assistant, Minkowski, performed the operation, and to their astonishment diabetes mellitus developed. Again no progress was made. Every type of extract of the pancreas was made with no result, until Laguesse (1893) *observed that ligature of the pancreatic duct in the dog* was attended by degeneration of the pancreas but not by diabetes mellitus.

Fig. 3—Thomas Willis (1622–1675).

This brings us to another method of research, where the scientist considers the data, evolves the solution, and then proceeds to the laboratory to prove his theory correct. This method practically never works. The usual result is that the investigator comes to the wrong conclusion, and the experiments which he devised prove something entirely unsuspected. The case of Frederick Banting (fig. 4), however, is one of the brilliant exceptions to this rule.

Banting was born at Alliston, Ontario, in 1891 entered the University of Toronto in 1912. His were interrupted by the war, but he was sent back complete them. After the war he became resident surgery at the Hospital for Sick Children, Toronto, specialised in orthopædic surgery. In 1920 he became part-time demonstrator at the University of W Ontario and did some research work in the departm of physiology.

It was at this time that he studied the literature on diabetes, and on the basis of the facts then known was able to predicate the solution of the problem. As he states (Banting and Best 1922):

> "he read an article dealing with the relation of the isle of Langerhans to diabetes. From the passage in this article which gives a résumé of degenerative changes in the acini of the pancreas following ligation of the ducts, the idea presented itself that since the acinous, but not the islet tissue degenerates after this operation, advantage might be taken of this fact to prepare an active extract of islet tissue. The subsidiary hypothesis was that trypsinogen or one of its derivatives was antagonistic to the internal secretion of the gland."

He therefore predicated that, if one took a dog, tied its pancreatic duct, and waited 7–10 weeks for degeneration of the pancreas, with disappearance of the trypsin, an ice-cold Ringer's extraction of the pancreatic remnants should contain the active principle. He obtained permission from Professor Macleod to conduct this experiment, together with C. H. Best, and it was completely successful and proved to be the turning-point in the history of diabetes. A special research department was eventually created, and Banting became its director. He was noted for his great kindness in helping and encouraging young research-workers. He had many interests besides his medical work, and was one of Canada's finest amateur painters. Unfortunately he met his death in an aeroplane accident while carrying out research into altitude effects during the late war.

Fig. 4—Frederick Banting (1891–1941).

VITAMIN C

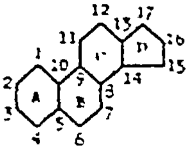
Yet another approach to a discovery is possible: where the research-worker sets out to discover a certain thing and discovers something completely different. An example of this is the work done by Szent-Györgyi which led to the isolation and characterisation of vitamin C. Szent-Györgyi in the early 1920's planned a detailed study of biological oxidation, in the hope that this might lead to an understanding of the function of the interrenal system. In 1928 he isolated from the adrenal cortex a powerful reducing substance, which he called hexuronic acid. This substance he also obtained from oranges and cabbages. He described some of its chemical properties. In 1932 he showed by animal experiments that this hexuronic acid had the same antiscorbutic activity as the substance found in fresh citrus fruits, and was in fact vitamin C or *l*-ascorbic acid.

SEX HORMONES

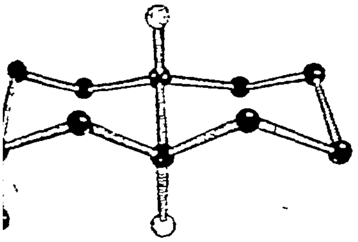
The history of the isolation and characterisation of the sex hormones illustrates yet another discipline of research. It shows how work done in another field, often academic and having apparently no bearing on the problem in hand, can often provide the necessary data without which the problem would remain insoluble.

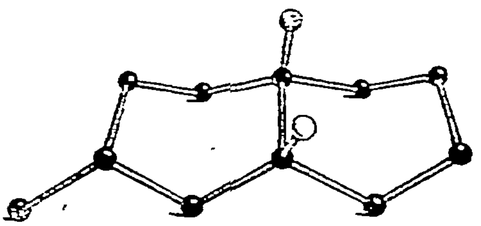
he effects of removal of the gonads in both male and ale animals have been known for centuries; and, the idea of internal secretions developed, it was lised that the sexual functions of both male and ale animals were regulated by chemical substances eted by the gonads. Attempts were made to isolate ive substances from ovarian tissue, and Allen and sy (1923) showed that the potency of such substances ld be tested on oöphorectomised rodents by the inal-smear technique of Stockard and Papanicolaou 17).

n the meantime, organic chemists and biochemists re greatly interested in the study of sterols, which are nd in the unsaponifiable fraction of fats of animals l of some plants and have a fatty character. They tain only carbon, hydrogen, and oxygen. Intensive dies conducted by Windaus (1932) in Gottingen and Wieland and Dane (1932) in Berlin showed that se substances consisted of a central nucleus to which ng side-chain was attached. It took much work ore the constitution of the central nucleus was covered, but finally the structure postulated by nheim and King (1932, 1933) was accepted:



This is known as the cyclopenteno nanthrene ring system. The carbon ms are numbered according to inter-tional practice, and the rings are tered. In the sterols the long side-in is attached in the 17-position, and sterols also have a hydroxyl group the 3-position and angle methyl groups in the 10-d 13-positions. This structure presents very complex blems of stereo-isomerism. Rings A and B are mpletely saturated, and it is possible to have two forms the rings according to the positions of the "points" the rings—i.e., carbon atoms 1 and 4, and 9 and 6. s the four valencies of the carbon atom correspond to e points of a regular tetrahedron, the "points" of the gs cannot be on the same plane, but may be either ore the plane of the paper or below. There are two ternative arrangements of this. In the first, one set points is above the plane of the paper and the other low: hence the rings present the appearance of a ir. This is called the trans-decalin arrangement, or e allo variety. In the second arrangement the points the rings are both on the same side of the plane of e paper, suggesting the appearance of two beds, and s is known as the cis-decalin or normal type. These o arrangements are illustrated by the perspective grams:

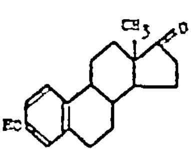




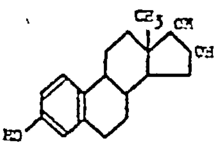
l natural sterols are of the allo or trans-decalin type. ereo-isomerism can also occur in the other rings and in e junctions of the various polar groups attached to the clens.

The work done by Windaus (1932) and Wieland and ane (1932) and by Rosenheim and King (1932, 1933) sterols was found to have an important bearing on e study of sex hormones. The first of these to be lated in crystalline form was the œstrogenic hormone, ich produces œstrus in female animals. The isolation s made possible by the discovery of Aschheim and ndek (1927) that large quantities of œstrogenic substances are excreted in the urine of pregnant animals. By 1932 five such substances had been isolated, by Butenandt (1929), Doisy et al. (1929), Marrian (1930), and Girard et al. (1932a and b), from this source and were found to have the same basic chemical structure as the sterols, but without the long side-chain at the 17-position. The formulæ are as follows:

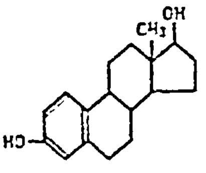
Œstrone

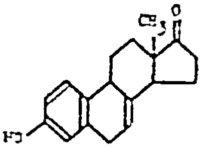


Œstriol

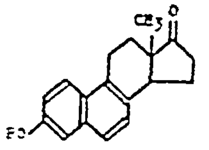


Œstradiol



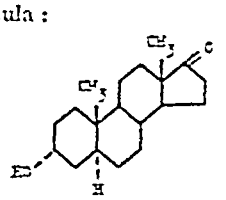


Equilin



Equilenin

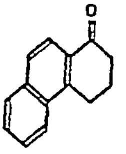
An androgenic substance, androsterone, was likewise isolated by Butenandt (1931) from male urine and found to have the following formula:



The question of stereo-isomerism in the œstrone molecule and the very complicated spatial arrangements of the more saturated members of this series render total synthesis impracticable at the present stage. Bachmann et al. (1940) have synthesised equilenine; but, great as this achievement is, it must be remembered that both rings A and B are unsaturated, and therefore the complicated spatial arrangement is ruled out.

For further progress in this field we must return to the pure organic chemistry of the sterols. It is to Ruzicka et al. (1934) that the credit belongs of first realising that the ready-made cyclopenteno phenanthrene nucleus could be obtained by cutting the side-chain off the sterols by chromic oxidation. Whereas Windaus and his colleagues concentrated their attention more on the side-chain, Ruzicka et al. (1934) realised the importance of the nucleus, and by suitable chemical operations they were able, by moving double bonds about and exchanging polar groups, to lay the foundations for the production from cholesterol of several hormones. Today testosterone, progesterone, desoxycorticosterone, and even œstrone and œstradiol are produced by this technique.

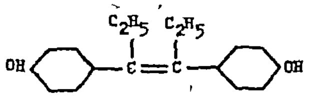
A rather different approach to the production of œstrogenic substances was suggested by the fact that no less than five such substances are produced in nature. It was decided to see how specific was the molecular structure for œstrogenic activity. Several phenanthrene compounds were made and tested, and the compound 1-keto-1:2:3:4-tetrahydrophenanthrene was found to have œstrogenic activity (Cook et al. 1934), though much less potent than the naturally occurring substances. The work was continued, and an important advance was the discovery that the phenanthrene structure was not essential for œstrogenic activity. Many compounds were made in an effort to produce simpler yet more potent substances. Finally the potency



of anol or *p*-hydroxy-propenyl benzene was tested and appeared to be very highly active:

Anol

However, when attempts were made to repeat the work, some batches of anol were found to possess only very slight activity, and it was obvious that the activity in the first batch must have been due to a contaminant. The work was continued in collaboration with Sir Robert Robinson, and finally the compound 4 : 4′-dihydroxy-α : β-diethyl stilbene, or stilbœstrol, was made and found to be very highly active.



This compound and the two related compounds, hexœstrol and dienœstrol, have found extensive use in the treatment of menopausal symptoms and other conditions for which formerly the naturally occurring œstrogens were prescribed. Their great advantage lies in the fact that they are cheap to produce and that they are active by mouth, and thus patients are spared much inconvenience and expense.

A further use has been found for these compounds in the treatment of carcinoma of the prostate gland. Huggins and Hodges (1941) showed that castration or the administration of œstrogens would bring symptomatic relief in a large proportion of cases and since then the compounds have been used extensively for this purpose. In about 95% of cases there is some response; and, in a large number of cases responding, complete symptomatic relief is obtained in a short time. The treatment can in no sense be described as a cure, since if treatment is discontinued the symptoms return, and in many cases the relief obtained is not permanent. However, it is the first time that a substance active by mouth has been found of use in the treatment of any form of cancer, and it offers to the patient with carcinoma of the prostate a definite hope of freedom from pain and discomfort at least for a time, and the possibility of resuming his normal activities.

A CALL FOR RESEARCH-WORKERS

The object of the founders of this series of Addison lectures, of which I have had the honour of giving the first, is to stimulate young workers to enter research, particularly research into the endocrine system. It is impossible for me to know whether the picture that I have painted in this brief period will have the effect of beckoning new people into the laboratory, or the reverse effect of scaring them away. I shall feel satisfied if I have dispelled the current idea of how a successful research is conducted.

It is practically impossible to convince students starting on research that such work is not for heaven-sent geniuses only. There is no doubt that successful research-workers tend to convey this impression to the outsider, because they follow the invariable scientific practice of writing their papers backwards, so to speak. When a research is finally published, it appears to the reader as an orderly series of steps carefully thought out; and if the reader is not already in the trade, the effect is to produce an acute inferiority complex in his mind and to persuade him that in no circumstances would he ever be able to conduct research.

My object in this lecture has been to show that research is never done as it is written, and that the cold orderly paper is produced practically always by a series of blundering steps in which the research-worker is rather like someone in a dark room scrambling for the switch and tripping over the furniture. When he has once found the switch and turned on the light, he can arrange the furniture in an orderly manner.

I think the justifiable conclusion is to go into laboratory and start work on something which you, refusing to be daunted by the great d that have gone before. Success depends mainly on amount of work that is done in the laboratory; though you may not succeed in discovering what set out to find, you can see from the account I have that you will always discover something.

ZYGOMATIC MASTOIDITIS

PHILIP READING
M.S. Lond., F.R.C.S.
SURGEON, THROAT AND EAR DEPARTMENT, GUY'S HOSPITAL, LONDON

ZYGOMATIC mastoiditis is not mentioned by Toynbee and Hinton, the pioneers of English otology. Only at the end of the second decade of this century did it gain general recognition, as the result of the publications of Mouret and Seigneurin (1920) and of Holmgren (1921).

During the course of a suppurative otomastoiditis infection may reach air cells in the root of the zygomatic process and there produce an inflammatory swelling. The path of the infection from the mastoid to the zygoma is generally along a preformed track of cells (Holmgren 1921, Gadolin 1938), though sometimes there appears to be no direct communication between the two groups of cells. Heine (1908) suggested that infection might pas direct from the attic vault to the diploë of the squam and so reach the temporal fossa. Horgan (1929) has suggested, as another possible route, the glaserian fissure, and Watson-Williams (1930) put forward the possibility that infection might track along a persistent petrosquamous sinus.

Of the 29 cases of zygomatic mastoiditis under review, a cellular mastoid was found in all but one of the 27 cases of acute infection. A cellular track was demonstrable in most of these. In both the cases of zygomatitis due to chronic infection, one of which was caused by actinocosis, the pus had apparently leaked through the roof the meatus.

CLINICAL PICTURE

All the cases reported in this paper presented with the auricular swelling as a prominent feature. Such swelling, ever, may appear as a complication after cortical stoidectomy. Horgan (1929) reported two, Rosenwasser d Druss (1933) four instances, and attributed them inadequate surgery at the first operation.

The greatest incidence is between the ages of 5 and years. The swelling develops in the course of a ppurative otomastoiditis and is commonest when such ections are common—in the late winter and early ing. A firm tumour covers the root of the zygoma d often causes œdema of the lower eyelid. It is tender, t fluctuation and "pointing" of the abscess are signs ng delayed in their appearance.

Trismus is an inconstant symptom. Pain and difficulty opening the jaws may be found in acute infection of e parotid gland and in inflammation of the skin of the terior wall of the meatus.

True zygomatic mastoiditis may be simulated by an scess in the pterygomaxillary space. Greenfield (1934) scribed such an abscess, which is very rare, and showed at it presented below the zygoma and caused severe smus. Mill (1932) showed an example of unusual gomatic infection, which, from the printed description, s probably of the same nature.

The differential diagnosis of acute zygomatic mastoiditis ay be rendered difficult by the frequent absence of one of e classical signs of suppuration in the middle-ear cleft—orrhœa.

ILLUSTRATIVE CASE-RECORD

A girl, aged 6 years, was admitted to hospital with a elling which had been growing in front of the ear for a rtnight. The swelling was firm, oval, and about $1\frac{1}{2}$ in. long, nd its general direction coincided with that of the zygomatic one. When it had first appeared there had been slight earache, ut so young a child was not able clearly to distinguish tween pain in the ear and pain in the adjacent swelling.

Examination of the tympanic membrane showed no normality. Tenderness could be elicited on pressure only er the zygomatic root. The solitary sign of aural disease as a slight impairment of the hearing on that side. No pus caped when the membrane was incised.

A cortical mastoidectomy was performed. The mastoid rocess was cellular. Grey swollen muco-endosteum was und in all the cells, and pus in the mastoid antrum. A achm of pus was liberated on opening the cells in the gomatic root.

CONDITION OF TYMPANIC MEMBRANE

Since this experience careful note was taken of the ndition of the tympanic membrane in all zygomatic nd other mastoid swellings.

Of the 27 patients with acute zygomatic mastoiditis, 3 had tympanic membranes scarcely distinguishable om normal. In 5 the membrane was injected and ightly bulging. In the remaining 9 otorrhœa was resent, and a perforation could be demonstrated in the ympanic membrane.

Impairment of hearing of varying degree was elicited n all. Those patients retained their hearing most who ad apparently the most healthy membranes.

This seemed to be an unusually high proportion of astoiditis without otorrhœa (66%). To obtain a control gure the records of other forms of acute mastoiditis ere studied. In the five years ending Dec. 31, 1945, 02 primary cortical mastoidectomies were performed. f these, 232 showed a superficial inflammatory swelling, aused by the underlying mastoiditis. Of these swellings 4 (10%) were centred over the zygoma, and 59, of which 5 (26%) were zygomatic, were not accompanied by otorrhœa. In 173 the mastoid swelling was associated with torrhœa, and zygomatitis accounted for 9 (5%) of these.

Thus 1 in every 4 cases of acute mastoiditis with superficial swelling had no perforation of the drumhead. Of those with no otorrhœa, 1 in every 4 had a swelling over the zygoma.

Beta hæmolytic streptococcus was found in 10 of the cases with no otorrhœa and alpha hæmolytic streptococcus in 3. Pneumococcus type III was not found in any.

If the total number of cortical mastoidectomies, 602, is taken as the basis of computation, zygomatic mastoiditis without otorrhœa was present in 2·4%, and all forms of mastoiditis without otorrhœa in 9·8%. This compares with the 5% of mastoiditis without otorrhœa reported by Watson-Williams (1929) in 300 simple mastoidectomies performed before the introduction of sulphonamides.

Sulphonamides had been given to 9 patients with zygomatic mastoiditis without otorrhœa, and to 6 with zygomatic mastoiditis and otorrhœa, before coming under observation. A study of the literature on zygomatitis will refute the suggestion that the absence of otorrhœa can be explained simply as a manifestation of "sulphonamide masking."

Heine (1908), speaking of swellings above and in front of the ear, said:

> "I have observed that these external signs were particularly well marked in cases in which the drum retained little or no sign of inflammatory change. The patients frequently state that, although they suffered from earache in the beginning, no discharge was noticed. This seems to suggest that the original trouble was a suppurative inflammation of the closed attic and that the pus found its way out directly without reaching the antrum or the mastoid cells."

More succinctly, Mouret and Seignourin (1920) wrote:

> "On apprendra que l'infection n'a fait que lécher la caisse, l'antre, avant de se localiser dans la région temporale."

A glance at the following table shows that otorrhœa is absent in a considerable number of cases and, also, that this absence is more frequent in the last two groups, which occurred within the sulphonamide era:

Author	*Zygomatitis without otorrhœa*	*Zygomatitis with otorrhœa*

Holmgren (1921)	2	10
Mollison (1922)	1	3
Rankin (1923)	1	2
Gadolin (1938)	7	32
Reading (present series) ..	18	9

Single case-records are not included, such as those of Neville (1933), Watson-Williams (1930), and Watt (1932). All these described otorrhœa as a feature of zygomatitis. Breitstein (1926) described a case without otorrhœa and drew attention to the lack of this symptom.

One can infer that, though the absence of otorrhœa is common in zygomatic mastoiditis, it has become more common since the introduction of sulphonamides.

No explanation of this absence of otorrhœa is apparent. Failing any other, we must accept the suggestion that, in a cellular mastoid with a cellular zygoma, early occlusion of the air cells and of the tympanum by swollen muco-endosteum allows the escape of pus by the only route left open, to the zygomatic root and the temporal fossa. At operation such thickening of the membrane could be demonstrated in the aditus of some but not all of the diseased mastoid bones.

SUMMARY

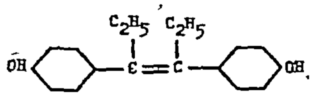
A review of 27 cases of acute zygomatic mastoiditis is presented.

Attention is drawn to the absence of otorrhœa in many acute zygomatic infections, and hence to the difficulties which may arise in diagnosis.

of anol or *p*-hydroxy-propenyl benzene was tested and appeared to be very highly active:

Anol

However, when attempts were made to repeat the work, some batches of anol were found to possess only very slight activity, and it was obvious that the activity in the first batch must have been due to a contaminant. The work was continued in collaboration with Sir Robert Robinson, and finally the compound 4 : 4′-dihydroxy-α : β-diethyl stilbene, or stilbœstrol, was made and found *to be very highly active.*



This compound and the two related compounds, hexœstrol and dienœstrol, have found extensive use in the treatment of menopausal symptoms and other conditions for which formerly the naturally occurring œstrogens were prescribed. Their great advantage lies in the fact that they are cheap to produce and that they are active by mouth, and thus patients are spared much inconvenience and expense.

A further use has been found for these compounds in the treatment of carcinoma of the prostate gland. Huggins and Hodges (1941) showed that castration or the administration of œstrogens would bring symptomatic relief in a large proportion of cases and since then the compounds have been used extensively for this purpose. In about 95% of cases there is some response; and, in a large number of cases responding, complete symptomatic relief is obtained in a short time. The treatment can in no sense be described as a cure, since if treatment is discontinued the symptoms return, and in many cases the relief obtained is not permanent. However, it is the first time that a substance active by mouth has been found of use in the treatment of any form of cancer, and it offers to the patient with carcinoma of the prostate a definite hope of freedom from pain and discomfort at least for a time, and the possibility of resuming his normal activities.

A CALL FOR RESEARCH-WORKERS

The object of the founders of this series of Addison lectures, of which I have had the honour of giving the first, is to stimulate young workers to enter research, particularly research into the endocrine system. It is impossible for me to know whether the picture that I have painted in this brief period will have the effect of beckoning new people into the laboratory, or the reverse effect of scaring them away. I shall feel satisfied if I have dispelled the current idea of how a successful research is conducted.

It is practically impossible to convince students starting on research that such work is not for heaven-sent geniuses only. There is no doubt that successful research-workers tend to convey this impression to the outsider, because they follow the invariable scientific practice of writing their papers backwards, so to speak. When a research is finally published, it appears to the reader as an orderly series of steps carefully thought out; and if the reader is not already in the trade, the effect is to produce an acute inferiority complex in his mind and to persuade him that in no circumstances would he ever be able to conduct research.

My object in this lecture has been to show that research is never done as it is written, and that the cold orderly paper is produced practically always by a series of blundering steps in which the research-worker is rather like someone in a dark room scrambling for the switch and tripping over the furniture. When he has once found the switch and turned on the light, he can arrange the furniture in an orderly manner.

I think the justifiable conclusion is to go into laboratory and start work on something which you, refusing to be daunted by the great that have gone before. Success depends mainly on amount of work that is done in the laboratory; though you may not succeed in discovering what set out to find, you can see from the account I have that you will always discover something.

ZYGOMATIC MASTOIDITIS

Philip Reading
M.S, Lond., F.R.C.S.
SURGEON, THROAT AND EAR DEPARTMENT, GUY'S HOSPITAL, LONDON

Zygomatic mastoiditis is not mentioned by Toynbee and Hinton, the pioneers of English otology. Only at the end of the second decade of this century did it gain general recognition, as the result of the publications of Mouret and Seigneurin (1920) and of Holmgren (1921).

During the course of a suppurative otomastoiditis infection may reach air cells in the root of the zygomatic process and there produce an inflammatory swelling. The path of the infection from the mastoid to the zygoma is generally along a preformed track of cells (Holmgren 1921, Gadolin 1938), though sometimes there appears to be no direct communication between the two groups of cells. Heine (1908) suggested that infection might pas direct from *the attic vault to the diploë of the* squam and so reach the temporal fossa. Horgan (1929) has suggested, as another possible route, the glaserian fissure, and Watson-Williams (1930) put forward the possibility that infection might track along a persistent petrosquamous sinus.

Of the 29 cases of zygomatic *mastoiditis under review,* a cellular mastoid was found in all but one of the 27 cases of acute infection. A cellular track was demonstrable in most of these. In both the cases of zygomatitis due to chronic infection, one of which was caused by actino-

Fig. 2—Increase of knee-jerk remaining after severance of central and lateral branches of crural nerve and due to hypertrophy of intact part of quadriceps. Maximum is reached 20–30 days after operation. In this rabbit the severed branches were prevented from reuniting. Compare figs. 4–6.

Fig. 3—Decrease of knee-jerk following severance of medial branch of crural nerve and of branch of gluteal nerve supplying tensor fasciæ latæ, in normal rabbit. Compare figs. 5 and 6.

by the quadriceps was used to effect an upward jerk. But with the animal unanæsthetised it is doubtful whether such methods would be sufficiently simple to warrant their use for frequent testing, and anæsthesia is impracticable because it affects these reflex responses in a manner impossible to standardise.

The method used by us to meet this difficulty has been to interrupt only part of the crural nerve, leaving intact the innervation of a portion of the quadriceps sufficient to overcome the inertia factor and give a very small jerk. The recovery of the other muscles can then be watched by noting any increase in the response after their reinnervation.

The main bulk of the muscles inserted on to the patella in the rabbit is innervated by the crural nerve, which splits up into lateral, central, and medial branches before entering the muscles. In most of our experiments the lateral and central branches were interrupted, leaving the medial branch intact. The muscles which that branch innervates, together with the tensor fasciæ latæ, whose nerve-supply is also left intact, give a response which is just perceptible when the limb is tested in the optimal position. It was expected that this would form a convenient base-line against which recovery of the other muscles could be watched. A complication, however, soon became apparent. In most of the animals the residual response—i.e., that due to the intact part of the quadriceps left to overcome the inertia factor—began to increase soon after operation, before the regenerating fibres could possibly be producing contraction in their muscles. Evidently the intact muscles undergo hypertrophy when excess work falls on them. That this was the true explanation was shown by experiments in which the parts of the nerve severed were not allowed to reunite. The intact portion of the quadriceps then increased in volume and weight, and the knee-jerk increased in extent, reaching a maximum 20–30 days after operation (fig. 2). The degree of hypertrophy is conditioned by the activity of the animal. Usually the increase was by 1–2 of our test units, but the limits of variation were wide, and one animal showed a hypertrophy of 6 units.

RESULTS

In spite of the difficulty produced by this phenomenon the technique allowed detection of the results of reinnervation of the paralysed muscles. When the central and lateral branches were crushed with smooth forceps 25 mm. from the quadriceps, it could be calculated that the regenerating fibres would again be able to produce contraction at about 30 days in the proximal parts and at 50 days in the distal parts of the muscles affected (Guttmann et al. 1942). It was during this period that a recovery of the response due to successful reinnervation became apparent and continued until the preoperation level was reached. There was then a period in which the response was maintained at a higher level than the mean value obtained before operation. This supernormal phase is interpreted as being due to responses which are the result of the reflex contraction tension developed by muscles which have undergone a completely successful reinnervation together with that developed by the intact hypertrophied muscles. After a while the response gradually declined back to the normal level, presumably owing to the disappearance of the hypertrophy (fig. 4).

That the reinnervation is completely successful after crushing of the nerve at one point in this way is shown by the fact that, when after several hundred days the muscles which were previously left intact were denervated, the response was reduced (fig. 5) by an amount comparable with the reduction which results if these muscles are denervated in a normal animal (fig. 3). Further, in eight animals all three branches of the crural were crushed, and the response recovered to the normal level in each case. In these experiments the response could first be detected 40–45 days after operation, the lag of 10–15 days being due to the initial reflex contraction tension developed having to overcome the inertia factor. After its first appearance the return back to the normal level was very rapid, usually being accomplished in about 10 days, and there was no supernormal phase.

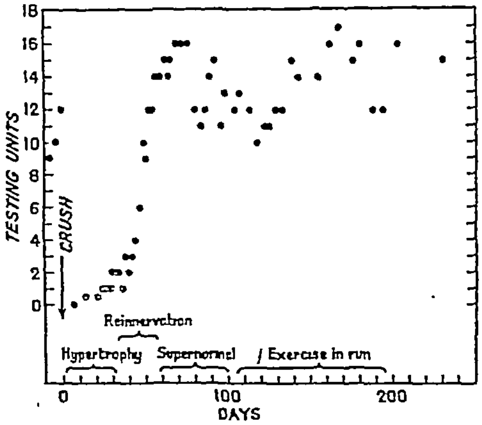

Fig. 4—Plots of knee-jerks in rabbit in which central and lateral branches of crural nerve had been crushed.

When the central and lateral branches were cut and their ends held together with cockerel plasma (Young and Medawar 1940), the recovery of the knee-jerk was very much less complete (fig. 6). Exaggeration of the residual response took place as before, and then 45–80 days after operation there were further increases in the response in eight animals, five others showing no signs of recovery. The magnitude of the response reached, or almost reached, preoperation levels in six cases, the maximum being attained after about 80 days. Apart from a temporary rise in the level of the response induced in most of the animals by a period of exercise in a run (figs. 4, 5, 6) there were no subsequent signs of increase.

At the end of considerable periods—398 days in one animal, 420 days in another—the muscles which had previously been left intact were denervated in those animals in which the response had reached the preoperation level (fig. 6). This led to a great reduction of the response, in striking contrast to the slight reduction caused by this denervation in normal animals and in the experiments where part of the crural nerve had been crushed. Thus, though the reflex response elicited after

"Sulphonamide masking," as an adequate explanation, can be partly discounted.

These patients were studied and treated at Selly Oak Hospital, Birmingham. To the medical superintendent of that hospital, Mr. R. P. S. Kelman, F.R.C.S., my thanks are due for his kind permission to publish.

RECOVERY OF STRETCH REFLEXES AFTER NERVE INJURY

D. Barker
B.A. Oxfd

J. Z. Young
M.A. Oxfd, F.R.S.

From the Department of Zoology and Comparative Anatomy, Oxford, and the Department of Anatomy, University College, London

In spite of the large amount of published work on the regeneration of nerve very little is known of the recovery of proprioceptor function. Since the functions of the various receptors of muscle in normal life are still largely unknown, it is impossible to estimate the importance of their recovery after nerve lesions, but it seems likely that some of the imperfections of muscle function after nerve suture are due to incomplete sensory reinnervation.

The only proprioceptor activities which it is easy to study experimentally or clinically are the stretch reflexes. The return of the ankle-jerk after nerve grafting has been described by Rezende (1942) in dogs and monkeys and by Davis et al. (1945) in cats; a division of the rabbit's crural nerve was made by Waller (1890) but seventeen months later the knee-jerk was still absent. Stopford (1930) reported the recovery of "joint sense" after nerve injury in man, this being a subjective term for a sense of whose receptors little is known.

Proprioceptor function is certainly not limited to response to stretching a muscle. The end-organs present in muscle include at least two chief types: muscle spindles and tendon organs. The stretch reflex is usually supposed to be mediated by the muscle spindles (Matthews 1933); but the evidence is incomplete, and it may well be that the excitatory afferent fibres belong to the tendon organs.

Histological investigation (Huber 1900, Tello 1907, Boeke 1916) has shown that there is some reinnervation of muscle spindles after nerve injury, but it remains uncertain whether the sensory and motor innervation are both restored. If all fibres become mingled at a point of nerve suture and no processes direct the regenerating fibres back into appropriate pathways, it is difficult to see how the normal pattern can be restored.

MEASUREMENT OF KNEE-JERK

We have devised a means of measuring the knee-jerk in the unanæsthetised rabbit in order to assess quantitatively its recovery after nerve injury.

The rabbit is placed on its back on a testing-couch in such a way that movement is possible only in the hind legs. When the patellar ligament is struck, the foot jerks upwards from where it has been resting on a horizontal rod, the height which it reaches being recorded by adjusting an upper rod to the level at which it is hit by the foot on almost every occasion that the reflex is elicited. The rods can slide a series of numbered holes, and by subtracting the depth of ankle from the total reading a measurement of the movement of the foot is obtained (fig. 1). As in subjects, the magnitude of the response is affected by conditions prevailing at the time of testing, but tests under conditions as standard as possible on successive give reasonably consistent readings with a no distributed variation.

It is thus possible to estimate the normal response then watch its recovery after interruption of the crural nerve.

A complication is introduced by the fact that, because of the weight of the shank and foot, a considerable amount of reflex contraction tension has to be developed by the quadriceps before any upward movement is possible. The height of the jerk elicited does not therefore give a linear measure of the force exerted by the muscles, even if the limb is placed in the same position at each test.

The term "inertia factor" has been given to that force which the quadriceps must exert to lift the weight the shank and foot and produce an upward movement which is just perceptible.

By transecting the quadriceps near its distal end attaching the tendon to a spring balance it has been to determine the magnitude of this force in different positions of the limb and to assess approximately its proportion of the total reflex contraction tension required for the normal response.

The tension required to elicit a slight movement in the usual testing position was 23–41% of that required to effect mean normal responses of 17–11 test units. Moreover, plots of the tension required to lift the limb to various heights showed that more work must be done in the earlier than in the later phase of lifting the leg. The same relationship between quadriceps tension and leg extension was found by Haxton (1945), who measured the forces involved in experiments on cadaver limbs.

The magnitude of the upward jerk cannot, therefore, be regarded as a linear index of the degree of recovery of the reflex after nerve injury; the return of a small response may represent a degree of recovery as high as 60%, for the muscles will have to develop enough contraction tension to overcome the inertia factor and to produce a visible jerk in that part of the upward swing where the greatest lifting forces are required to raise the ankle. The smallest detectable responses are those giving an upward jerk of about 3 mm. and fall between 0 and 1 test unit on the scale used; they are both difficult to elicit with certainty and to measure with accuracy.

Evidently it is desirable to devise some method of eliminating the inertia factor. Testing the animal the other way up to that which has been described, or testing with the animal held vertically, proved impracticable. It might be possible to devise some method of testing the animal on its back and counterweighting the limb so that all the reflex contraction tension developed

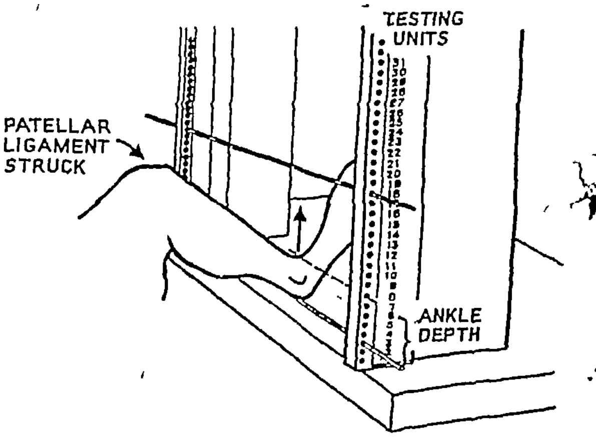

Fig. 1—Apparatus used to measure knee-jerk in unanæsthetised rabbit.

rceps, the knee-jerk fully recovers. Indeed, the covered response may be temporarily supernormal cause of a hypertrophy of the intact muscles.

When the whole crural nerve is crushed, there is full covery of the knee-jerk without a supernormal phase.

When two of the three branches were severed and united, five animals showed no visible recovery of the ıee-jerk, whereas eight showed a recovery of 19–70%. he recovery reaches a maximum soon after nerve-fibres ıve returned to the muscles, and does not increase ogressively thereafter.

When the entire crural nerve was cut and reunited, ıe recovery remained undetectable in nine cases, but two others slight knee-jerks reappeared, indicating velopment of over 50% of normal tension.

This investigation was assisted by a grant from the Medical esearch Council.

IRULENCE OF A STRAIN OF THE VOLE ACID-FAST BACILLUS (G564)

J. A. YOUNG
M.C., M.B. Edin., Dip. Bact.

J. S. PATERSON
Ph.D. Camb., M.R.C.V.S., D.V.S.M.

rom the Institute of Animal Pathology, University of Cambridge

DURING the past six years we have continued the investigation initiated by Griffith and Dalling (1940) into the value of the vole acid-fast bacillus as an immunising agent against infection with tuberculosis in cattle.

This investigation is still far from complete, and it would be unwise to attempt to formulate any conclusions at this stage; but, in view of some of our findings and the increasing interest in the vole strain as a potential living vaccine for human beings, we wish to issue a warning.

Most of our work has been done with strain LV285, isolated by Dr. A. S. Griffith in 1937 from material supplied by Dr. A. Q. Wells. In using this established laboratory strain we have encountered nothing which might indicate that it is not reasonably safe for use in cattle. For one experiment, however, we wished to try a more recently isolated strain, and Dr. Wells kindly supplied several primary cultures of strains from voles examined by him in the course of his work. The fact that we wished to use a vaccine prepared from a strain exposed to the minimal amount of growth on artificial media precluded any possibility of previous investigation of the strains by either Dr. Wells or ourselves, and the strain which we used was unselected except in so far as it grew rather better than the others in early subculture and so promised a larger yield. This strain has in our hands proved too dangerous for use as a vaccine.

RESULTS

In the experiment for which we required the recently isolated strain we lost two calves, one dying a month after vaccination, and the other having to be slaughtered in a moribund condition after eight weeks. The vaccinating dose consisted of 5 mg. of a seven-day-old culture inoculated intravenously, a dose which in the case of strain LV285 we have used in 142 animals, mostly young calves, without producing any ill results comparable with those in the two animals mentioned above. In neither animal were there macroscopic tuberculous lesions severe enough to cause death, but histological examination of the internal organs revealed widespread changes of a nature usually associated with tuberculosis, which justified the conclusion that death was directly attributable to the vaccine.

Though 15 other calves in the same experiment were similarly inoculated without apparent ill effects, the vole strain was recovered from 5 of these animals when they were slaughtered six months after a resistance test with virulent bovine bacilli, and the survival periods of the vole bacillus in two instances were 565 and 544 days.

The fact that in its immediate effects G564 is more virulent than LV285 is borne out by work on guineapigs.

In one experiment 20 guineapigs were vaccinated subcutaneously with 1 mg. of G564 in preparation for a resistance test to be carried out three months later. On the day that the resistance test was to be applied, 2 of the animals were unfit for inclusion in the experiment and were slaughtered for examination. Infection still persisted at the site of inoculation, the regional glands were enlarged and caseous, and there were numerous small lesions in various internal organs. A third vaccinated animal in the series died eighteen days after the resistance test, which consisted of 0·00001 mg. of virulent bovine bacilli inoculated intramuscularly. In this animal infection was even more pronounced than in the previous 2 animals, and both the morphology of the acid-fast bacilli found in the lesions and their subsequent culture showed that the lesions were due to the vole strain, though it is possible that there was some exacerbation of the lesions under the stimulus of the resistance test.

By themselves the unusually severe sequelæ described above would not have been unduly disturbing, for an avirulent tubercle strain can bring about a fatal result if used in too large a dose, and it might be that we were not allowing a sufficient margin for safety. We have, however, additional evidence on which to condemn the strain.

A rabbit was inoculated intravenously on Dec. 21, 1943, with 0·1 mg. of a seven-day-old culture of strain G564. It bore the inoculum well, and no ill effects were noted until the middle of 1946, when an abscess began to develop in its neck. The animal was slaughtered for examination on July 5, 1946. Besides actively progressive abscesses found in submaxillary and neighbouring cervical glands, in which many typical vole bacilli were found, there were small tuberculous lesions in the lungs and kidneys.

Another rabbit inoculated on the same date with 0·01 mg. intravenously also showed no ill effects until in August, 1946, it was reported to be leaving much of its food untouched. It was slaughtered for examination on August 27, 1946, when severe tuberculosis of the left testis, epididymis, and vas deferens was found. Many acid-fast bacilli of typically vole morphology were found. Old-standing lesions, some calcareous, were found in lungs, liver, kidneys, and one rudimentary mammary gland.

Numerous calcareous and caseocalcareous lesions were found in the liver and kidneys of still another rabbit, which accidentally injured itself on Oct. 8, 1946, and had to be destroyed. This animal had also been inoculated on Dec. 21, 1943, with 0·01 mg. intravenously. The vole bacillus was recovered in culture from the lesions after a survival period of 2 years and 291 days in the rabbit.

Two guineapigs inoculated intravenously, one with 0·1 mg. and the other with 0·01 mg., were killed 194 and 114 days after inoculation owing to the onset of paralysis in the hind legs. In neither of these animals were there well-defined macroscopic lesions in thoracic or abdominal organs, but in both the central nervous system was involved, with lesions in brain and cord, in which acid-fast bacilli of vole morphology were demonstrated in histological sections. But for the involvement of the central nervous system the lesions in these animals might well have been dismissed as trivial and regressive.

The last animal to be described is a guineapig inoculated subcutaneously with 1 mg. on July 4, 1944. When it was examined a month later there was a double ulcer nearly healed at the site of inoculation, and the regional glands were enlarged. It was examined again three months after inoculation, by which time the local lesion had healed and the swelling of the regional glands had subsided. So far as could be judged clinically this animal had recovered completely, and nothing was noted recovery following nerve suture appeared nearly normal, the reinnervation had evidently not been complete, and the hypertrophy of the intact muscles had to some extent persisted.

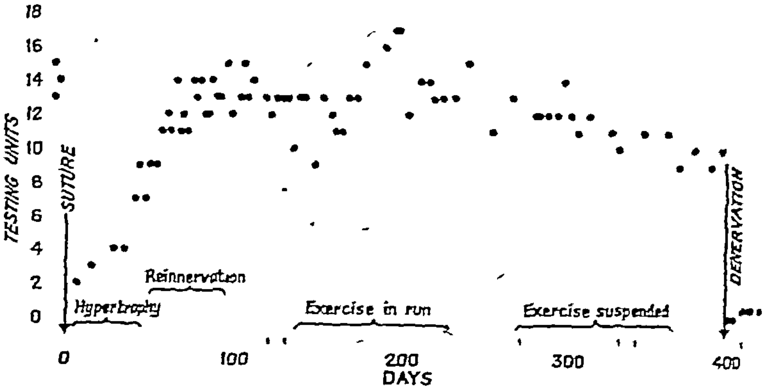

Fig. 6—Recovery of stretch reflex after central and lateral branches of crural nerve had been cut and sutured in a rabbit. Subsequent denervation of that part of the quadriceps previously left intact caused a great decrease of knee-jerk (cf. figs. 3 and 5). Recovery was about 40%.

One may assess approximately the degree of recovery of the stretch reflex after severance and suture by using a spring balance (see above) to determine the tensions represented by the magnitude of the response as it was recorded during the several phases of each experiment. To determine the tension developed by the muscles before operation, we first subtract the tension represented by the normal preoperation response from that represented by the response *immediately* after operation—i.e., before hypertrophy. The tension produced by the reinnervated muscles is represented by the response following severance of the nerve branches *originally* left intact and can then be expressed as a percentage of the normal. Thus, in one experiment the original response height was 13 units, representing 1150 g., and immediately after severance of the central and lateral branches the response was 2 units, equivalent to 490 g.; therefore the normal tension developed by those muscles innervated by the severed branches was 660 g. After reinnervation and recovery followed by a denervation of the muscles previously left intact, a response of 0–1 test unit, equivalent to 260 g., remained, representing a recovery of 39%. Similar calculations in four other animals in which there had been some increase of the response during the reinnervation period revealed a recovery of 19–70%. These figures are only approximate assessments; the variations are presumably correlated with differences in the closeness of apposition at the suture line, but detailed investigation of this has not yet been completed.

In eleven other animals the crural nerve was completely divided, the ends being united as well as possible with plasma or, in two experiments, with stitches. There was no return of a visible upward jerk in nine cases, though frequent tests were made in the 300 days which some of them were kept alive. A very slight response returned in the remaining two, which were kept alive for 149 and 532 days. Since a considerable amount of the recovered reflex contraction tension would have to be used to overcome the inertia factor in these experiments, the lack of a return of an upward jerk does not necessarily imply that there has been no recovery of the stretch reflex. The slight response which returned in the two animals represents a considerable recovery, of about 60%. In all these animals stimulation of the crural nerve at biopsy produced contraction of the quadriceps muscles.

These experiments therefore warn us that in the study of stretch reflexes the movement which can be elicited does not necessarily provide an index of the recovery of the nerve and muscles. Similar factors no doubt operate in the case of knee-jerks and ankle-jerks in man. By paying attention to the possible inertia factor it should be possible so to arrange the limb that even minimal stretch responses can be elicited.

When the crural nerve is interrupted by a crush lesion, the knee-jerk fully recovers. After severance of part of the nerve and suture, recovery may reach about 70% under ideal conditions but is very variable, presumably in correlation with the closeness of union of the severed stumps. Even after complete division of the nerve, when good unions are difficult to obtain, recovery of about 60% of the normal tension may take place.

These relatively good recoveries are surprising when one considers that both the sensory and motor pathways of the reflex have been interrupted. It is hoped that histological investigation of the muscles removed from these animals will show whether the muscle spindles have become reinnervated to an extent sufficient to make it likely that they are the stretch receptors. Some spindles undoubtedly receive sensory and others motor reinnervation, but preliminary results make it very doubtful whether any considerable number of spindles recover the full innervation after nerve suture.

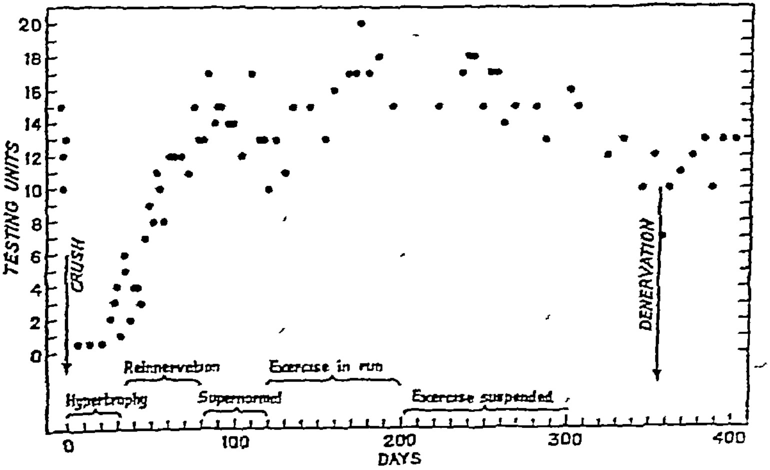

Fig. 5—Recovery of stretch reflex after central and lateral branches of crural nerve had been crushed in a rabbit. *Subsequent denervation of that part of the quadriceps* previously left intact caused only a slight decrease of knee-jerk, as in normal animal (fig. 3), showing that recovery *in those muscles affected by the crush* was complete.

SUMMARY

The extent of movement of the leg in the knee-jerk is not a linear function of the tension developed in the quadriceps muscles. Considerable tension must be developed before any movement can take place. Therefore, when the muscles are reinnervated after nerve injury, a recovery of 50% may be insufficient to produce any visible knee-jerk.

If two of the three branches of the crural nerve of the rabbit are interrupted, that part of the quadriceps which remains intact is just able to overcome this "inertia factor" and produce a small knee-jerk. Hypertrophy of the intact part of the muscle may then lead to a considerable increase of this residual jerk.

When two of the three crural branches are interrupted by crushing with smooth orceps, the knee-jerk fully recovers. Indeed, the ecovered response may be temporarily supernormal ecause of a hypertrophy of the intact muscles.

When the whole crural nerve is crushed, there is full ecovery of the knee-jerk without a supernormal phase.

When two of the three branches were severed and eunited, five animals showed no visible recovery of the nee-jerk, whereas eight showed a recovery of 19–70%. he recovery reaches a maximum soon after nerve-fibres ave returned to the muscles, and does not increase rogressively thereafter.

When the entire crural nerve was cut and reunited, he recovery remained undetectable in nine cases, but n two others slight knee-jerks reappeared, indicating levelopment of over 50% of normal tension.

This investigation was assisted by a grant from the Medical Research Council.

VIRULENCE OF A STRAIN OF THE VOLE ACID-FAST BACILLUS (G564)

J. A. Young
M.C., M.B. Edin., Dip. Bact.

J. S. Paterson
Ph.D. Camb., M.R.C.V.S., D.V.S.M.

From the Institute of Animal Pathology, University of Cambridge

During the past six years we have continued the investigation initiated by Griffith and Dalling (1940) into the value of the vole acid-fast bacillus as an immunising agent against infection with tuberculosis in cattle.

This investigation is still far from complete, and it would be unwise to attempt to formulate any conclusions at this stage; but, in view of some of our findings and the increasing interest in the vole strain as a potential living vaccine for human beings, we wish to issue a warning.

Most of our work has been done with strain LV285, isolated by Dr. A. St. Griffith in 1937 from material supplied by Dr. A. Q. Wells. In using this established laboratory strain we have encountered nothing which might indicate that it is not reasonably safe for use in cattle. For one experiment, however, we wished to try a more recently isolated strain, and Dr. Wells kindly supplied several primary cultures of strains from voles examined by him in the course of his work. The fact that we wished to use a vaccine prepared from a strain exposed to the minimal amount of growth on artificial media precluded any possibility of previous investigation of the strains by either Dr. Wells or ourselves, and the strain which we used was unselected except in so far as it grew rather better than the others in early subculture and so promised a larger yield. This strain has in our hands proved too dangerous for use as a vaccine.

RESULTS

In the experiment for which we required the recently isolated strain we lost two calves, one dying a month after vaccination, and the other having to be slaughtered in a moribund condition after eight weeks. The vaccinating dose consisted of 5 mg. of a seven-day-old culture inoculated intravenously, a dose which in the case of strain LV285 we have used in 142 animals, mostly young calves, without producing any ill results comparable with those in the two animals mentioned above. In neither animal were there macroscopic tuberculous lesions severe enough to cause death, but histological examination of the internal organs revealed widespread changes of a nature usually associated with tuberculosis, which justified the conclusion that death was directly attributable to the vaccine.

Though 15 other calves in the same experiment were similarly inoculated without apparent ill effects, the vole strain was recovered from 5 of these animals when they were slaughtered six months after a resistance test with virulent bovine bacilli, and the survival periods of the vole bacillus in two instances were 565 and 544 days.

The fact that in its immediate effects G564 is more virulent than LV285 is borne out by work on guineapigs.

In one experiment 20 guineapigs were vaccinated subcutaneously with 1 mg. of G564 in preparation for a resistance test to be carried out three months later. On the day that the resistance test was to be applied, 2 of the animals were unfit for inclusion in the experiment and were slaughtered for examination. Infection still persisted at the site of inoculation, the regional glands were enlarged and caseous, and there were numerous small lesions in various internal organs. A third vaccinated animal in the series died eighteen days after the resistance test, which consisted of 0·00001 mg. of virulent bovine bacilli inoculated intramuscularly. In this animal infection was even more pronounced than in the previous 2 animals, and both the morphology of the acid-fast bacilli found in the lesions and their subsequent culture showed that the lesions were due to the vole strain, though it is possible that there was some exacerbation of the lesions under the stimulus of the resistance test.

By themselves the unusually severe sequelæ described above would not have been unduly disturbing, for an avirulent tubercle strain can bring about a fatal result if used in too large a dose, and it might be that we were not allowing a sufficient margin for safety. We have, however, additional evidence on which to condemn the strain.

A rabbit was inoculated intravenously on Dec. 21, 1943, with 0·1 mg. of a seven-day-old culture of strain G564. It bore the inoculum well, and no ill effects were noted until the middle of 1946, when an abscess began to develop in its neck. The animal was slaughtered for examination on July 5, 1946. Besides actively progressive abscesses found in submaxillary and neighbouring cervical glands, in which many typical vole bacilli were found, there were small tuberculous lesions in the lungs and kidneys.

Another rabbit inoculated on the same date with 0·01 mg. intravenously also showed no ill effects until in August, 1946, it was reported to be leaving much of its food untouched. It was slaughtered for examination on August 27, 1946, when severe tuberculosis of the left testis, epididymis, and vas deferens was found. Many acid-fast bacilli of typically vole morphology were found. Old-standing lesions, some calcareous, were found in lungs, liver, kidneys, and one rudimentary mammary gland.

Numerous calcareous and caseocalcareous lesions were found in the liver and kidneys of still another rabbit, which accidentally injured itself on Oct. 8, 1946, and had to be destroyed. This animal had also been inoculated on Dec. 21, 1943, with 0·01 mg. intravenously. The vole bacillus was recovered in culture from the lesions after a survival period of 2 years and 291 days in the rabbit.

Two guineapigs inoculated intravenously, one with 0·1 mg. and the other with 0·01 mg., were killed 194 and 114 days after inoculation owing to the onset of paralysis in the hind legs. In neither of these animals were there well-defined macroscopic lesions in thoracic or abdominal organs, but in both the central nervous system was involved, with lesions in brain and cord, in which acid-fast bacilli of vole morphology were demonstrated in histological sections. But for the involvement of the central nervous system the lesions in these animals might well have been dismissed as trivial and regressive.

The last animal to be described is a guineapig inoculated subcutaneously with 1 mg. on July 4, 1944. When it was examined a month later there was a double ulcer nearly healed at the site of inoculation, and the regional glands were enlarged. It was examined again three months after inoculation, by which time the local lesion had healed and the swelling of the regional glands had subsided. So far as could be judged clinically this animal had recovered completely, and nothing was noted until August, 1946, when it showed signs of being paralysed in one leg. It was killed for examination on August 22, 1946, 2 years and 49 days after inoculation, when it was found that the subcutaneous tissues of the lower portion of the abdomen were infiltrated with a firm granulomatous material, every lymphatic gland in the body was enlarged, there were numerous small necrotic foci in liver and spleen, and there was a tuberculous lesion invading the substance of the cerebellum, in which acid-fast bacilli of vole morphology could be demonstrated in histological sections.

DISCUSSION

It is clear from our results that the use of the vole acid-fast bacillus as a living vaccine is not unattended by risk, and that no strain intended for use in man should be used before exhaustive tests have been made to determine its virulence and powers of resistance.

We find it difficult to believe that G564 is an exceptional strain and very different from all the other strains which have been studied, and we suggest that the virulence tests reported by the various workers who have contributed to the scanty literature on the subject have not been carried out in a manner likely to determine the highest possible virulence of the strains which they were using. We suggest that the cultures have been too old, that many of the animals have been tuberculin tested, and that the animals have not been left sufficiently long.

The cultures used by Wells and Brooke (1940) were two months old, by Brooke and Day (1944) eight weeks old, and by Corper and Cohn (1943) and Birkhaug (1946) six weeks old. Griffith (1942) did not state the age of the cultures from which his inocula were prepared, but it was by his advice that we adopted the use of seven-day-old cultures only for all our work. A seven-day-old culture is much more likely to contain a high proportion of viable bacilli than one six or eight weeks old.

We can see no point in tuberculin testing animals used for virulence tests. It can do no good and may do harm. We have found it necessary to tuberculin test our experimental cattle because it is essential to learn the limits and duration of the skin reactions in vaccinated animals to obtain a standard for use in field work, but we have never used tuberculin on any of our smaller laboratory animals inoculated for either virulence or protection tests.

With regard to the period over which the inoculated animals should be kept for observation, it is clear that the apparently trivial and regressive lesions noted in some animals killed after three to eighteen months must be reconsidered in a new light. In some of these lesions acid-fast organisms have been demonstrated microscopically, but they have not grown in culture. This, however, is no proof that the focus is completely inactive, for we have recovered the vole strain from this type of lesion by passage through the Orkney vole when direct cultures from the same site have proved sterile. It seems possible that as immunity wanes (apparently in 2–2½ years in small animals) there may be a recrudescence of activity in these foci and a severe and progressive infection. Three years would not be too long for a minimal period of observation in virulence tests on strains intended for vaccine work in man.

SUMMARY

Severe sequelæ have been observed in calves, rabbits, and guineapigs inoculated with strain G564 of the vole acid-fast bacillus.

No strain of the acid-fast bacillus should be used as a living vaccine in man before exhaustive tests have been made to determine the highest virulence which it is capable of attaining.

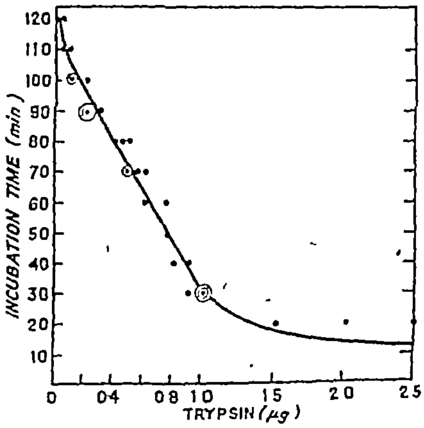
RELEASE OF PROTEOLYTIC ENZYME IN ANAPHYLACTIC AND PEPTONE SHOCK IN VITRO

GEORGES UNGAR
M.D., D.Sc. Paris

From the Department of Chemical Pathology, University College Hospital Medical School, London

IT is now well established that histamine is released in anaphylactic and anaphylactoid shock and is the main factor responsible for the symptoms observed in these conditions. The next step in investigating the cause of shock is to explain the mechanism of histamine release. Since there is some evidence that histamine release is connected with proteolysis (Dragstedt 1941, Feldberg 1941, Rocha e Silva 1944), experiments have been made to find out whether proteolysis can be detected when sensitised tissue and homologous antigen are mixed, or peptone added to normal tissue, in vitro.



Titration curve of crystalline trypsin: abscissa, amounts of trypsin acting on 5 mg. of fibrinogen in 5 ml. of buffer (pH 7·6) solution; ordinate, incubation time which prevents clotting of the mixture on addition of thrombin; circles, two or three identical results.

METHODS

Proteolytic enzyme activity was estimated by a technique based on the very sensitive method described by Ferguson (1943), using fibrinogen as substrate and its clotting by thrombin as indicator.

To 2·5 ml. of a 0·2% solution of fibrinogen* in buffered saline (pH 7·6) 2·5 ml. of the solution or tissue suspension to be tested is added, and the mixture is incubated at 38°C. Every ten minutes 0·4 ml. of the mixture is removed and tested for clotting with one drop of a 1% solution of thrombin.* The end-point of the protease estimation is reached when the fibrinogen does not clot within fifteen minutes after addition of thrombin.

The results are compared with a titration curve obtained by using crystalline trypsin† and expressed in units. The unit chosen was the amount of enzyme which prevented the clotting of fibrinogen, in the conditions described above, after thirty minutes' incubation. This unit was 1 μg. of crystalline trypsin in the total volume of 5 ml.

As shown in the accompanying figure, the titration curve is practically a straight line between 0·1 and 1·0 unit, and only this part of the curve was used for estimations. When the end-point was reached before thirty minutes, the estimation was carried out on dilutions of the original solution.

Serum-antiprotease was estimated by a method based on the same principle.

A solution was prepared containing 1 unit of trypsin per ml. of saline. Amounts of 0·08 ml. of this solution were distributed in a series of small tubes to which was added 0·08 ml. of the serum to be tested diluted to 10^{-1}, 10^{-2}, 10^{-3}, and 10^{-4} for preliminary estimation. The mixtures were made up to 0·2 ml. with saline and incubated for thirty minutes.

After this pre-incubation, which ensured the optimal combination of enzyme and anti-enzyme, each tube received

---

* Human fibrinogen and human thrombin, as issued by the Lister Institute, were kindly supplied by R. A. Kekwick, D.SC.

† Crystalline trypsin was prepared and kindly supplied by Mrs. C. E. Work, PH.D. It contained 41% of $MgSO_4$, and its activity was 0·139 T.U. per mg. protein N at 37°C.

0·2 ml. of the 0·2% solution of fibrinogen, and incubation was continued for a further thirty minutes.

The tubes were then tested with one drop of thrombin. In the tubes where clotting took place it could be assumed that the trypsin was neutralised by the antiprotease of the serum.

The final *estimation* was then done by the same method by adding to 0·08 ml. of trypsin decreasing amounts (from 0·08 ml. to 0·008 ml.) of the lowest concentration of serum which still allowed the clotting of fibrinogen. The unit of antiprotease was chosen as the amount of serum which, under the given conditions, neutralised 1 unit of protease.

Guineapigs were used in all the experiments. Anaphylactic sensitisation was induced by a single subcutaneous injection of 10 mg. of egg albumin (dried egg white). The animals were stunned and killed by bleeding 19–60 days after sensitisation. The blood was allowed to clot, and the serum was collected and tested within 6–24 hours. Immediately after the death of the animal the lungs, kidneys, and liver were excised and minced with fine scissors. In each case 1 g. wet weight of the tissue was suspended in 2·5 ml. of a solution of the antigen in saline (usually 10 mg.). The control consisted of a suspension of the same tissue in saline without antigen. To each suspension 2·5 ml. of the fibrinogen solution was added, and the mixture incubated.

In the peptone experiments the same tissues were used, but taken from normal guineapigs, and suspended in 2·5 ml. of a neutralised solution of bacteriological peptone (usually 25 mg.).

In each experiment the antiprotease titre of the serum was determined, and 1 ml. of the same serum was mixed with 1 ml. of the antigen or peptone solution and incubated for fifteen minutes at 38°C. After incubation the antiprotease titre of the mixture was estimated (taking into account that the serum had been diluted twice). If dilution has an effect in dissociating the protease-antiprotease complex, as is assumed by Macfarlane and Pilling (1946), it would presumably affect both the experimental and control samples equally.

TABLE I—RELEASE OF PROTEASE FROM TISSUES AND DECREASE IN SERUM-ANTIPROTEASE BY CONTACT OF ANTIGEN IN VITRO

RESULTS

Table I summarises the results obtained on adding the antigen in vitro to tissue suspensions or serum of sensitised guineapigs. They show that release of free protease can be detected in these animals from the 19th to 45th days after sensitisation. The mean values of enzyme released were 0·44 unit (± 0·1 S.E.) in the liver, 0·35 unit (± 0·04) in the kidney, and 0·3 unit (± 0·05) in the lung. Addition of antigen to serum causes a fall of antiprotease by an average of 68% (± 11). After the 45th day (experiments 12 and 13) there is neither liberation of enzyme nor decrease of anti-enzyme. Experiments 3 and 4 show that excess of antigen inhibits the release of enzyme. This is probably mainly due to the antiprotease effect of egg albumin (Grob 1943). In experiment 8 the guineapig did not respond to the optimal amount of antigen. Three non-sensitised guineapigs (experiments 14, 15, and 16) were tested with negative results. In experiments 9 and 10 the tissue suspensions were filtered fifteen minutes after the addition of antigen, and protease estimation was done on the filtrate. The results obtained under these conditions were identical with those given by the unfiltered samples, showing that enzyme release takes place within fifteen minutes of contact with the antigen.

Table II shows that the addition of peptone to tissue suspensions and to serum has a greater effect than anaphylaxis in vitro. The mean amounts of enzyme released were 4·625 units (± 2 S.E.) in liver, 0·665 unit (± 0·07) in kidney, and 0·59 unit (± 0·07) in lung. Serum antiprotease was reduced by an average of 78% (± 4). In experiment 21 the guineapig did not respond to peptone, and it is worth noting that the resistant animal had an unusually high antiprotease level.

No enzyme could be detected in the controls, except in three cases where liver suspension was slightly active, probably owing to mechanical release of cell proteases.

The mean antiprotease level in guineapig serum was 1325 units (± 180) per ml. There was no significant difference between sensitised and normal animals. This contradicts the observations of Burdon (1942), who found, by a different method, a rise in antiprotease during sensitisation.

DISCUSSION

Some of the early theories of anaphylactic shock assumed the intervention of a proteolytic enzyme set free from its combination with an anti-enzyme. Jobling and Petersen (1914) showed that the antiprotease could be adsorbed by adding various agents to serum, but they could not show that this happened in anaphylactic shock. In fact, there was little valid evidence in favour of the enzyme theory of anaphylaxis, and when in 1922 Dale and Kellaway reviewed the problem they could justifiably exclude proteolysis from the factors leading to shock.

The last few years, however, have brought new data allowing the reintroduction of proteolysis into the mechanism of anaphylactic shock. Rocha e Silva (1939) showed that injection of trypsin gave rise to a condition indistinguishable from anaphylactic shock. This was confirmed by Arellano et al. (1940). Recent studies of fibrinolysis have brought further evidence. Fibrinolysis was discovered by Dastre (1893), and its connexion with peptone shock was first established by Nolf (1905). Rocha e Silva et al. (1946), by eliminating the effect of heparin, showed that fibrinolysis was a constant feature of anaphylactic and peptone shock in dogs. All the evidence given by Tagnon (1942), Christensen and MacLeod (1945), Macfarlane and Pilling (1946), and Christensen (1946) supports the view that fibrinolysis is brought about by a proteolytic enzyme similar to, but distinct from, trypsin.

It is usually admitted that blood-protease is normally bound to antiprotease, and that proteolysis takes place when antiprotease is put out of action and protease is set free. A different conception tends to be accepted now, mainly as an outcome of studies on streptococcal fibrinolysin. This conception, as expressed by Christensen and MacLeod (1945), assumes that blood-protease exists normally as an inactive pro-enzyme, comparable to pancreatic trypsinogen. In various circumstances the pro-enzyme could be activated by a hypothetical kinase. There is, however, no evidence at present that blood contains this pro-enzyme, or that it undergoes activation by a kinase (with the possible exception of the special case of streptococcal fibrinolysin). Activation can be explained by the setting free of the protease from its combination with the anti-enzyme. Combination between protease and antiprotease is probably not a simple reaction but requires the presence of one or possibly several other substances (Ungar 1945). Protease can accordingly be released by several mechanisms involving various components of the anti-enzyme complex.

The experiments described here cannot decide whether protease liberation is an essential feature of anaphylactic and peptone shock. Only minute amounts of enzyme were detected in the experimental conditions described above, and injection of these amounts would certainly not lead to shock in vivo. It is possible, however, that the quantities of enzyme really released are greater than the amounts detected. There is some evidence that protease release is a result of an explosive reaction (experiments 9 and 10 with filtered tissue suspensions), and that the enzyme recombines afterwards with the anti-enzyme. In a few experiments serum was left in contact with peptone for twenty-four hours, and the antiprotease titre was estimated at intervals. An hour after addition it was found to be 10% of the control, three hours later 60%, twenty-four hours later 100%. It is therefore likely that recombination takes place during the protease estimation and reduces the amount of detectable free enzyme.

Protease is released also in tissues which do not release histamine under the same conditions. Addition of antigen to lung or kidney of sensitised guineapigs releases appreciable amounts of histamine (Ungar and Parrot 1936, 1937, Schild 1939), but guineapig liver does not release histamine. This may be due to the difference in the amounts of histamine available in the tissues.

Another fact that requires explanation is the better response of tissues to peptone than to antigen in vitro, whereas in vivo peptone causes only a mild shock in guineapigs, contrasting with the high mortality in true anaphylactic shock.

SUMMARY

When specific antigen was added to tissues of sensitised guineapigs, protease was liberated. The same results were obtained by adding peptone to normal guineapig tissues.

At the same time a fall of the antiprotease titre was observed in serum to which antigen or peptone had been added.

The inference of these findings on the mechanism of anaphylactic and peptone shock is discussed.

I wish to thank Prof. C. Rimington for much valuable advice and for the kind hospitality offered in his laboratory, and Dr. M. Rocha e Silva for his helpful criticism.

FAILURE OF OIL-SOLUBLE ANÆSTHETICS TO GIVE PROLONGED ANALGESIA

MICHAEL KELLY.
M.D. Adelaide

From the Department of Anatomy and Histology, University of Melbourne

OILY solutions for protracted local analgesia were first suggested by Yeomans et al. in 1928. Under various names, butyl *p*-aminobenzoate and benzocaine dissolved in olive oil are recommended for pruritus ani and fissure in ano, and for relieving pain after proctological operations. They can be used also for painful states such as fibrositis and neuralgia.

Butyl *p*-aminobenzoate is almost completely insoluble in water, whereas benzocaine is soluble only to the extent of 1 in 2500 (Martindale 1941). Both are readily soluble in oil, and it is assumed that the oil after injection will hold the agents in solution rather than yield them to the tissues.

Some of the earlier products caused pain on injection (Morgan 1935), and an improvement was made by adding a water-soluble agent, such as procaine, which secures immediate analgesia.

Having occasion to inject subcutaneously over the tibia a 3% solution of benzocaine in oil, I noted that analgesia of both skin and periosteum appeared within 2 min., and that sensibility had returned to normal 24 hours later. This observation was in contrast with the claim made in the manufacturer's brochure that the effects would last 14 days.

The formulæ of two of the most popular of these products are as follows:

'*B.A.B.A.N.*'	Ethocaine	1 part
	Butyl *p*-aminobenzoate ..	1 part
	Benzocaine	6 parts
	Benzyl alcohol	5 parts
	Olive oil to	100 parts
'*Proctocaine*'	Procaine	1·5 parts
	Butyl *p*-aminobenzoate ..	6 parts
	Benzyl alcohol ..	5 parts
	Olive oil to	100 parts

After careful observations on several patients, I satisfied myself that the analgesia produced by these agents did not last longer than a few hours.

EXPERIMENTS

I therefore performed the following experiment on myself several times:

3 c.cm. of the agent (proctocaine or B.A.B.A.N.) was introduced under the skin over the tibia so as to occupy a circular area 3 in. in diameter. The injection was painless, and the area of skin, which was slightly bulged by the oil, became totally anæsthetic within 20 sec. So also did the periosteum immediately beneath. But the anæsthesia lasted only 3 hours, and afterwards cutaneous sensation was normal; and the periosteum was abnormally tender for a few days.

For 48 hours a mild throbbing pain was felt in this area, and the skin was itchy for 3 or 4 days. The swelling due to the oil was distinctly visible for 10 days, and the subcutaneous tissues pitted on pressure. No diminution of cutaneous sensibility could be detected.

On one occasion the saphenous nerve trunk was interrupted by chance, giving a larger area of anæsthesia below the middle of the tibia on its medial side. In less than 2 hours, however, it had returned to normal.

No significant difference was observed between the effects of the two agents. The duration and degree of analgesia and the subsequent reactions were the same in both cases.

DISCUSSION

Duncan and Jarvis (1943), who blocked the facial nerves of cats with different oily solutions, reported that a mixture of procaine and butyl *p*-aminobenzoate caused a nerve block of only 3 hours' duration. Paralysis lasting 2 or 3 weeks was secured only with solutions containing 10% of benzyl alcohol, and they showed that the fibres of the facial nerve had degenerated and regenerated within this time. Benzyl alcohol in 5% solution produced little effect.

The observations of Duncan and Jarvis suggest a reason for the early claims made for oil-soluble local anæsthetics: these contained high concentrations of benzyl alcohol, which brought about degeneration of the nerve filaments and analgesia lasting several weeks. In the later solutions smaller quantities of benzyl alcohol were used, and the pharmacological effect of the earlier preparations was not obtained. Because of insufficient experimental support, however, claims have been made which cannot be substantiated.

The fact that oily solutions have been in constant use for a decade makes the more surprising their failure to live up to the claims made for them. Few have been heard to question their efficacy, since the reasons advanced on their behalf seemed convincing enough. The oil, it has been thought, would refuse to yield to the tissues the reagents which are soluble in oil but not in water. But the body fats and lipoid constituents of cells have been forgotten; and the mere fact that butyl *p*-aminobenzoate produces anæsthesia means that it is not inert but combines with some essential element of the nervous tissues. The question of solubility in water is irrelevant.

OIL AS A VEHICLE FOR OTHER AGENTS

There are many reasons for questioning the value of oil as a vehicle for the injection of therapeutic agents. It is recommended for the administration of drugs whose slow absorption is desirable. But theelin and stilbœstrol are absorbed in an unpredictable way after intramuscular injection of oily solutions (Emery et al. 1942, Emery and Matthews 1943, Brown et al. 1944). Bray (1943) found oil an unreliable vehicle for adrenaline, for absorption may be as rapid as from watery solutions, and deaths have been reported from overdosage. Freyberg (1942), who extensively investigated the use of gold salts in rheumatism, found that the insoluble salts were not absorbed at all, whether suspended in water or in oil, and that the absorption of the soluble salts was delayed only slightly by the use of oil as a vehicle. "At best," said Duncan and Jarvis, "the oil can be regarded only as a source of annoyance because of its slow absorption and the danger of improper injection."

SUMMARY

Experiments have demonstrated that the claims made on behalf of oil-soluble local anæsthetics cannot be substantiated, for the analgesia secured by subcutaneous injection lasts only 3 hours.

It is doubtful if oil has any general value as a vehicle for prolonging the action of therapeutic agents after subcutaneous or intramuscular injection.

Financial assistance from the National Health and Medical Research Council of Australia is gratefully acknowledged.

SALMONELLA ENTERITIDIS INFECTION

ASSOCIATED WITH USE OF ANTI-RODENT "VIRUS"

J. G. DATHAN
M.R.C.S., D.C.H.
CLINICAL ASSISTANT, ROYAL LIVERPOOL CHILDREN'S HOSPITAL

A. J. MCCALL

PATHOLOGIST, NORTH STAFFS ROYAL INFIRMARY

JEAN ORR-EWING *
B.M. Oxfd

JOAN TAYLOR
M.B. Lond., D.P.H.
DIRECTOR, SALMONELLA REFERENCE LABORATORY, COLINDALE

IN a household of five children and three adults, a "virus" preparation was used three times for the extermination of mice. About ten days after its last use some members of the household were found to be infected with *Salmonella enteritidis*.

CASE-HISTORIES

CASE 1.—Towards the end of May, 1944, R. D., a well-developed and previously healthy boy, aged $3^1/_2$ years, complained of tiredness. He was flushed, with temperature 99·6°F and pulse-rate 100. He continued to have a daily rise of temperature to 100°F until September, 1944, when after immunotransfusion the temperature subsided. Occasional rises of temperature to 100°F were noted from November, 1944, to March, 1945, though the child was then clinically well.

On examination in May, 1944, no abnormal physical signs were detected. Towards the end of June the heart apex-beat became more forcible and was palpable in the midclavicular line; a soft systolic apical murmur developed. In July the systolic murmur became much louder and rougher, and the heart was thought to be slightly enlarged to the left. There was slight fullness in the epigastrium and tenderness in the gall-bladder region, though the spleen was never palpable. At no time did the child have diarrhœa. Radiography of the chest, Vollmer patch test, and Mantoux test gave negative results.

Laboratory Findings.—*S. enteritidis* var. *jena* was isolated three times in June, but not afterwards. Serum taken in the fourth week of the illness agglutinated *S. enteritidis* H to 1/125, O to 1/125. These titres gradually fell till, during the tenth week, the serum did not agglutinate *S. enteritidis* H but agglutinated O to 1/50. Blood-culture was sterile on three separate occasions.

A blood-count showed red cells 4,630,000 per c.mm., Hb 79% (12·36 g. per 100 c.cm.), colour-index 0·86, white cells

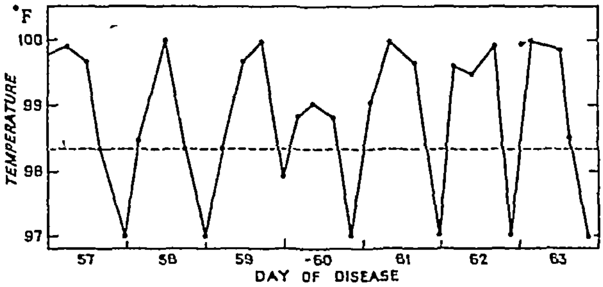
---

* Miss Orr-Ewing died before this work was completed.

5800 per c.mm. (polymorphs 41%, eosinophils 3%, lymphocytes 52%, monocytes 4%). The sedimentation-rate was 10 mm. in first hour (Wintrobe: corrected for anæmia). Blood-counts and sedimentation-rates showed no significant change throughout the illness.

The urine was normal.

Treatment.—It was thought that there might be a residual *S. enteritidis* infection of the gall-bladder causing the continued pyrexia. Hexamine gr. 40 was given daily without effect. Sulphadiazine 2·5 g. daily was also without effect. Finally the mother was immunised with a vaccine from the *S. enteritidis* strain isolated, and bled when her serum showed titres of 1 : 500 H and 1 : 250 O for the organism. An immunotransfusion of 300 ml. was then given to case 1. Four days later the temperature gradually fell and the general condition improved. At the same time the cardiac impulse became more normal, though there was still an apical systolic murmur. The clinical condition remained good, but some pyrexia continued until March, 1945.



Temperature chart of case I.

CASE 2.—At about the start of the illness of case 1, a baby, aged 7 months, had a sharp attack of diarrhœa, lasting a week, with blood and mucus in the stools. *S. enteritidis* was isolated from the stools three weeks after the attack, but was not demonstrable a week later. There was no pyrexia. The serum was not examined for agglutinins.

After the recognition of these two cases, the fæces and blood of the remaining members of the household were examined.

CASE 3.—The serum of a boy, aged 10 years, agglutinated *S. enteritidis* H at 1/125 and O at 1/25. Stool cultures were negative. It was then recollected that this child had had a very mild attack of diarrhœa about three weeks previously.

CASE 4.—In a girl, aged 11 years, no symptoms were observed, but the serum on June 23, 1944, agglutinated *S. enteritidis* H at 1/25 and O at 1/25. Stool cultures were negative.

The three adults in the house and the remaining child gave negative agglutination reactions, and a single stool culture from each was negative.

DIAGNOSIS

It is clear, from the bacteriological and serological evidence of case 1, that the prolonged pyrexia that characterised this illness began with an intestinal infection by *S. enteritidis*, though there was no diarrhœa or vomiting. The persistence of the pyrexia for so long after the organisms had ceased to be demonstrable in the stools requires explanation; and, though we can reach no definite conclusions, two suggestions may be considered: (1) the persistence of *S. enteritidis* infection outside the alimentary tract, or (2) the unstable nature of the child's thermoregulatory mechanism, together with the debility and slight anæmia that followed the initial infection.

In support of the first suggestion there is evidence that *S. enteritidis* may produce systemic infection. Many cases have now been described of septicæmia and typhoid-like illnesses that were attributed to infection by this organism. Rosher and Wilson (1921) and Guthrie and Montgomery (1939) have given references. Probably some of the earlier cases attributed to *S. enteritidis* were due to *S. enteritidis* Dublin, for this organism was not clearly distinguished from *S. enteritidis* until 1 (White). However, in the fatal cases of infantile with meningitis and cholecystitis described by and Montgomery the organism was clearly identified *S. enteritidis*. It may be noted that, in the typhoid-li illness described by Rosher and Wilson, a blood-culture and several stool cultures were negative, though the serological evidence pointed almost conclusively to *S. enteritidis* infection.

Also noteworthy is the observation that in case 1 the daily temperature chart from June 6 exhibited a characteristic and constant pattern (see figure) when *S. enteritidis* could be isolated from the stools, and this temperature pattern was maintained for about three months during which stool cultures were negative. This suggests that the initial cause of the pyrexia was still operating and was independent of intestinal infection.

Though striking improvement followed blood-transfusion, we are doubtful how far this should be attributed to the transference of artificially induced antibody.

SOURCE OF INFECTION

All members of the family were questioned about previous attacks of diarrhœa, the food eaten, and the possibility of food having been contaminated by vermin. It was found that between three weeks and ten days before the onset of pyrexia in case 1 a commercial "virus" preparation had been used for the extermination of mice. The preparation was used according to the directions, and bait soaked in the "virus" was left about the house. No member of the household was seen to touch the bait, but, about two weeks before the onset of symptoms, R. D. (case 1) was seen playing with the empty bottle in which the "virus" was supplied. No other possible source of infection was discovered.

BACTERIOLOGY

The strains of *S. enteritidis* isolated from cases 1 and 2 were investigated antigenically and found to be typical, having the formula IX, XII; g,m.... They were subjected to special biochemical tests with Bitter's glucose, rhamnose, arabinose, and dulcitol, and Stern's glycerol medium. The reactions subdivide the enteritidis species into four main varieties (Kauffmann 1935): (1) *jena*, responsible for human infections; (2) *danysz*, isolated from natural rodent infections; (3) *chaco*, isolated from men during the Chaco war; and (4) *essen*, isolated from man and ducks. The two strains isolated from cases 1 and 2 were of the *jena* variety.

As several anti-rodent "viruses" are known to contain living *S. enteritidis*, the preparation used in this household was investigated. The preparation labelled "mice" had been bought "over the counter"; it was supplied in a carton in which were three screw-capped bottles containing a semi-solid material. The instructions on the label were as follows:

> "Mix the liquid with sufficient stale bread or any cereal food favoured by the rodents to make a crumbly paste. Use a clean basin and a spoon for the purpose. Distribute all the bait at night close to the runs as soon as it has been mixed. Do not use after (date). Do not touch the bait with the bare hands, as rats and mice are very suspicious. Remove other food which may attract the rodents. The whole contents of the bottle must be used as soon as it is opened."

One of the bottles had been used, but swabs from it yielded *S. enteritidis* var. *jena*. R. D. had been seen handling this bottle. The second bottle was half empty; cultures from this material yielded *S. enteritidis* var. *jena*, a chromogenic coccus, and other organisms. The third bottle was unopened; on testing it yielded a pure growth of *S. enteritidis* var. *jena*, all the colonies of which appeared to be smooth to the naked eye. Ten of these olonies were tested with acriflavine (Pampana 1933); ne only of these gave a pure smooth reaction, so that the ulture was partially rough. A 24-hour broth culture as made from the "virus." When 0·1 ml. of this ulture was injected intraperitoneally into each of three ice all died in 48–108 hours, and *S. enteritidis* var. *jena* as recovered from spleen and heart blood.

DISCUSSION

Leslie (1942) tested six different commercial anti-rodent "virus" preparations, four of which contained *S. enteritidis* var. *danysz*, and two *S. enteritidis* var. *jena*. He found the "virus" preparation labelled "rats and mice" to be *S. enteritidis* var. *danysz*. We confirmed this finding, but the "virus" labelled "mice," prepared by the same firm, yielded *S. enteritidis* var. *jena*.

It has been recognised that these preparations may be a source of danger to man, either directly or as the result of contamination of food by the excreta of vermin infected with the virus (Ministry of Health 1933). Cases of enteritis, some fatal, attributed to "virus" preparations, have been described: that reported by Kristensen and Bojlén (1931) is the latest. Scott (1933) described an outbreak of food-poisoning due to *S. enteritidis* involving 38 people, with 1 fatal case, in which the food was probably infected by mice. A "virus" containing *S. enteritidis* had been used in the establishment, and this organism was isolated from apparently healthy mice on the premises.

In the series here reported there was strong presumptive evidence that the "virus" was the source of the infecting organism. There was no indication from the instructions on the bottle that this preparation may be dangerous to man, or that utensils used in the preparation of the bait should not be used for the preparation of human or animal food—an omission which should certainly be remedied.

SUMMARY

An outbreak of infection with *S. enteritidis* var. *jena* is described in which four children were involved.

An anti-rodent "virus" preparation containing an identical organism was being used in the house at the time of the outbreak, and was probably the source of the infecting organism.

"... The increasing availability of money for research in medicine is beginning to embarrass our medical schools. Where is the trained personnel coming from to make use of these funds? ... There seems to be a widespread public belief in what might be called the magic-wand theory of medical advance.... According to this theory, our research laboratories stand ready at any time to turn money into scientific discoveries; in other words the bottleneck to further advance is the lack of funds; with adequate funds we can buy a cure for cancer or infantile paralysis or any other disease which afflicts mankind. The bottleneck, of course, is not the lack of funds; it is the lack of capable and thoroughly trained investigators to use the funds. The medical schools, to which we must look for these investigators, do not possess and cannot now obtain the fundamental facilities through which alone this increasing demand can be met. Indeed, many of our medical schools are in the position of a cook asked to prepare a wedding feast for which the champagne has been furnished but no water to boil the potatoes."—Mr. RAYMOND B. FOSDICK in the Rockefeller Foundation review of work for 1946, p. 23.

Reviews of Books

Dimensions of Personality

H. J. EYSENCK, PH.D., with a foreword by Prof. A. J. LEWIS, M.D. London: Kegan Paul, Trench, Trubner. 1947. Pp. 308. 25*s.*

THIS book records the results of testing 700 neurotic Service personnel at the Mill Hill Hospital by tests elaborated from those of psychological laboratories, and relating these results with the psychiatric traits recorded from each patient's personal history and symptoms. Briefly, a factorial analysis of thirty-nine traits has enabled two factors to be described. One, a general factor of neuroticism (associated with a badly organised personality, unsatisfactory parents or home, and general asthenia), and the other a bipolar factor with dysthymic tendencies at one end (affective states, obsessional traits, an autonomic lability), contrasted with hysterical symptoms, hypochondriacal complaints, low intelligence, sex anomalies, poor performance of finicky tasks, and good sense of humour (as defined) at the other. These two types can be contrasted throughout on physique, on dark-vision tests, on choline-esterase tests, on their aims, on the fluidity or rigidity of their outlook, and on body build (the dysthymics showed predominance of linear, hysterics of lateral growth, while as a whole neurotics were more leptomorph than normals). Dysthymics were found to be slightly more suggestible than hysterics. A useful variation of the complicated Rorschach test is described, and showed significant differences between normals and neurotics, and between serious and mild neurotics.

Dr. Eysenck and his collaborators have been most searching in checking their results mathematically, ensuring that only significant differences are recorded, and usually studying sufficiently large control groups. Their mass of evidence is formidable but welcome: it brings into psychiatry the method of mathematics and gives hope that we can be more accurate in our assessments, more certain in our pronouncements. But it would be a pity if Dr. Eysenck's modest claims led to facile statements by the less well trained—e.g., that "long persons are essentially neurotic" or "dull persons are potentially hysteric." Nor has he quietened all doubts. He seems himself to be too dogmatic in what he says of graphology, and those who are not allied too closely to the theory of type-identity will wish to know what happens in Dr. Eysenck's future assessment of the man who, at Mill Hill, was a conversion-hysteric and has now become suicidal and depressed, or of the apparent depressive whom electrical convulsive treatment has apparently (as it does sometimes) converted into a querulous somatic pain-ridden "hysteric." The apparent rigidity of some of the diagnoses—which he admits—points to the critical spirit in which this book must be received, but such a spirit should also appreciate the fresh channels of thought which it opens, and which Dr. Eysenck's team will clearly continue to provide.

Industrial Toxicology

ALICE HAMILTON, A.M., M.D., assistant professor of industrial medicine Emeritus, Harvard University; and RUTHERFORD T. JOHNSTONE, M.D., director of department of occupational diseases, Golden State Hospital, California. London: Oxford University Press. 1946. Pp. 186. 15*s.*

TEXTBOOKS on industrial toxicology do not usually deal with the treatment of cases of poisoning, probably because industrial medicine is preventive rather than curative in outlook. But the general practitioner needs to know how to treat cases of poisoning and this book contains a good section on treatment. Dr. Alice Hamilton, who has done pioneer work on industrial toxicology in the United States, sums up the known facts capably, giving much thought and space to the pathology and diagnosis of the really important poisonings, such as those by benzol, lead, and carbon monoxide. Dr. Rutherford Johnstone in a foreword to his section on treatment and prevention reminds us that "inability to eradicate completely occupational ill-health arises from the constant introduction of new substances with which the management and the medical profession are not familiar or the failure of small plants to maintain a program of medical supervision or hygiene." New occupational diseases are therefore bound to appear from time to time. Full details are given of the principles underlying the treatment of industrial poisonings together with practical therapeutic measures. The book can be recommended as both authoritative and easy to read.

Diagnosis and Treatment of Pulmonary Tuberculosis

MOSES J. STONE, M.D., assistant professor in medicine, Boston University; PAUL DUFAULT, M.D., F.A.C.P., superintendent, Rutland State Sanatorium, Massachusetts. London: H. Kimpton. 1946. Pp. 316. 17*s.* 6*d.*

"IN the British Isles, where tuberculosis is widespread in dairy-herds and pasteurisation rather exceptional, human tuberculosis of bovine origin is higher than in any other country in the world." Home-truths like this, encountered casually in a discussion on infection, give the British reader a disquieting jolt and cause him to reflect how salutary it is to read a "foreign" textbook occasionally, to see what students of another nationality are being taught. He will find that there are inevitably differences in approach and differences in the interpretation of factual evidence. Quite often he will find differences in the factual evidence itself; and these are by no means necessarily due to faulty or prejudiced observation. More and more fully is it being realised that tuberculosis varies geographically in its manifestations. Even in Great Britain morbidity and mortality rates vary from county to county and city to city, and the prognosis for a Yorkshireman with tuberculosis is noticeably better than that of a patient from Wales. It is therefore not surprising that there should be apparent discrepancies between the British, American, and Scandinavian concepts of the disease process. Erythema nodosum, for example, spells primary tuberculous infection in Scandinavia; in Britain it is regarded as a non-specific allergic reaction, but highly suggestive of tuberculosis; in this American textbook it is nowhere mentioned. Indeed the authors seem to pay scant attention to primary tuberculous infection in childhood, and its significance in adult life is barely mentioned except in a barmecidal chapter-heading: whereby questions are ignored which in Europe are regarded as crucially important in any campaign against the disease.

By our standards too, clinical examination is dismissed somewhat perfunctorily in eleven depreciatory pages. The student's surprising question, "When should we percuss? and auscult?" is answered equally surprisingly, "Every time you examine a new (sic) chest." Evidently all subsequent examinations should be radiological or biochemical. And yet surely it is common experience that physical signs developing over a radiologically proven lesion, hitherto silent, can draw attention to changes in that lesion earlier than they can be perceived in serial X-ray films? Among the "indications" for surgical operations it is startling to find phrenic paralysis and pneumoperitoneum regarded as "at best a palliative measure in advanced and almost hopeless bilateral cases." The techniques for all the different operative measures are faithfully described, but no underlying philosophy of adjuvant therapy is divulged—no indication as to whether the desiderata be the radiological disappearance of cavities or sputum conversion.

With much of the book, however, one cannot fail to be in complete and enthusiastic agreement. The chapter presenting Diseases which Simulate Tuberculosis more than compensates for deficiencies elsewhere (which after all may be due only to shift of emphasis and so more apparent than real). The section on Intrathoracic Dynamics (that formidable controversial topic!) is perhaps the least satisfactory. Much is far from lucid and in parts it is baffling. Can an intrapleural vacuum ever be anything else than subatmospheric? And surely to state that ultraviolet rays penetrate deeper than infra-red rays (whose action is "rather superficial and physical") is to contradict the consistent findings of Sonne, Coblentz, Bachem and Reed, and a host of other workers? At the end of each chapter, besides the references mentioned in the text, a list of works for "suggested reading" is supplied, which should prove helpful to the interested (or puzzled) student.

Studies on the Influenza A Epidemic of March 1941 at Groningen (Holland)

J. A. R. VAN BRUGGEN, M.D.; L. BIJLMER, M.D.; W. HOEK; J. MULDER, M.D.; L. J. ZIELSTRA. P[illegible] of the Institute of Preventive Medicine, Leyden, no. [illegible] 1947. Pp. 64. 10*s.*

THE epidemiological behaviour of influenza in H[illegible] during the war years seems to have differed c[illegible]ably *from that in Britain.* Thus the winter of 1940–4 afforded the sharpest epidemic of recent years, whereas *that of 1943–44* passed with only a moderate outbreak—the converse of British experience. Two-thirds of this monograph is an account of the clinical features of cases of uncomplicated influenza and of cases of pneumonia, the remaining third describing laboratory work on the virus strains recovered from the cases and on sera from the patients. This work was done on ferrets and mice: 5 strains of a virus related to the W.S. strain of influenza A were recovered, and serological tests showed *that* patients convalescent from influenza developed increase in neutralising and complement-fixing antibodies to the W.S. virus. The authors clearly think that the influenza virus plays an important part in causing the pulmonary complications seen during influenza epidemics: they were able to recover virus from the sputum of a patient with staphylococcal and streptococcal pneumonia and a patient with pneumococcal pneumonia, and from the throat washings of a patient with pneumococcal bronchitis. In their remaining cases however, the evidence for the existence of a virus in *addition to a bacterial infection of the lung* is inadequate, consisting merely in the demonstration of antibodies to influenza virus in the serum during convalescence.

Penicillin in General Practice (2nd ed. London: Staples Press. 1947. Pp. 110. 5*s.*).—This little book by Dr. J. L. Hamilton-Paterson provides an accurate, complete, and readable account of penicillin treatment as practised today.

The New-born Infant (3rd ed. London: H. Kimpton 1945. Pp. 314. 16*s.* 6*d.*), covering the first 6–8 weeks of life, is written by Dr. Emerson L. Stone, associate clinical professor of obstetrics and gynæcology at Yale. He describes fully the physiology, management, and pathology of the neonatal *period. He tries to discourage the perpetuation* of error, to sift new practices, and to survey published work; and his long experience informs the book. Some sections—such as that on congenital heart disease—could have been better left to specialists, and at this date it will not do to say of meningitis that serum is indicated for meningococcal infection, while for other types treatment is not specific. But the book is good and useful.

Poisons: Their Properties, Chemical Identification, Symptoms and Emergency Treatments (New York: D. van Nostrand. London: Macmillan. 1946. Pp. 209. 16*s.* 6*d.*).—This new compendium of poisons, their elementary chemistry, commonplace sources, lay symptomatology, and emergency treatment is designed by Vincent J. Brookes (sergeant in the New Jersey State police) and Hubert N. Alyea (associate professor of chemistry in Princetown University) for quick reference by those who may find the medical handbooks on the subject too technical or insufficiently practical. *Arrangement in alphabetical order*, a glossary, and some conversion tables increase its usefulness to the ambulance and first-aid officer, the police, and the casualty staff—and to doctors who hold classes in the subject.

Local Anæsthesia: Brachial Plexus (2nd ed. Oxford: Blackwell Scientific Publications. *1947. Pp. 56. 10s. 6d.*).—The copiously illustrated method described by Prof. R. R. Macintosh and Dr. W. W. Mushin in *their first edition* is retained. Those unfamiliar with the technique of injecting the stellate ganglion are reminded that by including sympathetic block while injecting the brachial plexus they will relieve vascular spasm of the upper limb. *Repeated small* injections—each preceded by an aspiration test—are now advocated, in place of continuous injection of the anæsthetic solution during the withdrawal of the first needle—which is in close proximity to the subclavian artery. *This modification* in technique should eliminate all risk of an intravascular injection.

ORAL VITAMIN D

in Lupus Vulgaris

Lupus vulgaris, though uncommon, is of such chronic nature that there always exists a pool of affected patients who constitute a serious social problem.

Recent success in the treatment of lupus by massive oral dosage of vitamin D is therefore of great significance. Backed by local therapy, administration of High Potency Ostelin Tablets (calciferol) has evoked rapid response in many cases. A high proportion of cures has been reported even amongst cases of many years' standing.

Normal dosage is 150,000 i.u. daily, supplied by three High Potency Ostelin Tablets. The usual dose is well received by most patients and toxic symptoms when they occur are generally mild; treatment, of course, should be adequately supervised.

Tablets (50,000 i.u.) 25's and 100's.
Dispensing size 1,000.
Ampoules (300,000 i.u.) 6 x 1 cc.

High Potency OSTELIN

A new Antispasmodic Sedative

NEURO-TRASENTIN

REGISTERED TRADE MARK

It is recognised that spastic conditions of the hollow viscera are frequently associated with nervous or psychic factors.

NEURO-TRASENTIN

antispasmodic and sedative, a combination of Trasentin, clinically effective in the treatment of spastic conditions, and phenobarbitone B.P. acts by

- **Direct action on smooth muscle.**
- **Indirect action by blocking motor impulses to spastic muscle.**
- **Sedation of the central nervous system.**

Neuro-Trasentin Tablets contain 0·03 g. (½ gr.) Trasentin, hexahydro-diphenylacetyl-diethylamino-ethanolester hydrochloride and 0·02 g. (⅓ gr.) phenobarbitone B.P. in bottles of 20 and 100.

LONDON: SATURDAY, MAY 24, 1947

On the Record

A FAMOUS American foundation, before granting funds to any hospital, insists on examining its records office. In this country we often pay too little attention to this department's work, as witness the small space allotted to its meagre staff, the casual overflow of documents into the cellar, and the methods of filing, each different from the other except that all have been inherited from a bygone generation.

The first purpose of records is of course to serve the patient, not only while he is in hospital but after he has left it: they may be needed, for example, to settle a claim for compensation, or when he returns for readmission. Next, they supply the governing body with a picture of the hospital's activities, and hospital administrators with a guide to the probable case-load of each department; regionally, they may help planners to decide the number of beds needed for each purpose, and centrally they can furnish an overall picture of trends in disease. Finally they can aid research not only into particular entities but also into the social origin and course of morbidity. Though causes of death have been registrable for a hundred years, there has never been any comparable index of the diseases that handicap without killing, and such an index is unobtainable without at least a complete return from all hospitals. Since 1944 the Bureau of Health and Sickness Records at Oxford, using punch-cards for a continuous record of all hospital admissions in the area of the Oxford and District Joint Hospitals Board, has brought to light information never before obtained in this country, and there is some hope that a start will be made by extending the Oxford experiment to cover hospitals all over the country. For such a survey to succeed, however, the hospitals will have to overhaul their practice to fit it for this new work; and by so doing they will enhance their own efficiency.

Inertia, local prejudice, and fear of expense mark the attitude of many hospitals to their records office; unlike any other hospital department, this is usually directed by someone who has had no special training and has been given no chance to compare the local system with others. Hence the Oxford proposal to provide courses for hospital records officers, equipping them, like the American "medical record librarians," to help clinicians both as experts on the form and size of records and as statistical advisers. Records officers could, in turn, be helped by ending needless reduplication of their work. Relief could, for example, be given by uniting the dates of annual returns: at present the records of many hospitals must be twice checked each year—for clinical returns at the end of the calendar year, and for financial returns at the end of the financial year.

Any system of recording and filing should aim at standardisation and simplicity, and have regard to future needs. Everybody agrees that the jumble of papers now known as the patient's "notes" should give place to forms of uniform size, held together and following each other in a settled order: but opinion is less unanimous on how to file them. Many statisticians and most clinical research-workers favour the unit record system, by which the notes for one patient are collected in a single file; but others prefer the binding of notes in chronological order, to prevent loss and ensure ready access. There is perhaps room for both systems, and possibly for others, the choice depending on the type of hospital and particularly on its readmission-rate. It is, however, noteworthy that a progressive county-council hospital in Middlesex has operated the binding system successfully since 1927, despite a readmission-rate higher than in teaching hospitals; and the staff, who include research-workers continually referring to the notes, emphatically favour binding. Working from a card-index file showing on one card the first and all subsequent admissions, they can find in a minute any note taken in the last twenty years, and 1000 full case-notes, recorded on paper of uniform size and bound in volumes of about 100, occupy only two feet of shelf. The experience of such a hospital, where the question of records has been carefully studied, should be valuable to others who are trying to evolve the system best suited to their needs, and visitors to this one in Middlesex will also find many of the incidental arrangements interesting.

For example it is the records officer who answers telephone inquiries about the condition of patients: and she who undertakes all the administrative work following a death, ranging from interviews with relatives to arrangements in connexion with an inquest. In the wards a 90% saving in forms has followed the replacement of the sister's weekly indent by a weekly visit from the storekeeper, who restocks a small cabinet. In the outpatients' department the use of coloured stars on the patient's personal card and on the notes has eliminated confusion between different departments and doctors; while the wise use of code-numbers has saved space and aided "at-a-glance" reference.

The ideal to which attention is now being given is the making of a birth-to-death health record for every person in the country. These could be kept at registries—perhaps one in each region—whose first function would be to supply data about patients whose notes were lost or whose previous history was uncertain. Any breach of confidence which the existence of such a registry might be taken to imply might possibly be overcome by storing the notes under numbers, the keys to which would be held only by the contributing hospitals and practitioners, and the patients. The hospitals could then make their contribution to the registry with little extra labour by submitting a carbon copy of the report sent to the general practitioner on the patient's discharge, which should be comprehensive and approved by the responsible member of the staff and should of course fit the envelope used for the practitioner's own notes. The contribution from the general practitioner himself would be less easily made: if, as seems probable, he must continue to write his own notes, the only additional work that can reasonably be asked of him is that of making a simultaneous carbon copy; and a carbon copy made with a pen might well be illegible. Again, if his own notes were copied by an unskilled typist errors might creep in; and a legible but wrong report is worse than none at all. Perhaps the best solution would be a typewritten abstract, prepared by a trained clerk at yearly intervals and initialled by the doctor, one copy going to the registry and the other, if it relates to illnesses now ended, superseding the previous year's notes, which would be filed for reference.

Opinions may differ on the advisability, or practicability, of central or regional registries, just as they differ on the technique of recording by hospital and practitioner. This, however, need not prevent early agreement on many important subjects, including the training of records officers, the classification under which diseases are to be tabulated, and the size and order of record and report sheets. A really good system of records, making the least possible demands on his time and temper, is one of the things that the doctor has a right to expect from a National Health Service; but he will have to help to create it.

The Vole Acid-fast Bacillus

SINCE 1937, when A. Q. WELLS reported[1] the occurrence of tuberculosis in the wild vole, *Microtus agrestis*, the investigation of this type of tuberculosis has gone steadily forward in spite of considerable war difficulties, and now WELLS[2] has brought together the results achieved in a memorandum issued from the Sir William Dunn School of Pathology in Oxford where much of the work has been done. The disease has been found in voles sent from nineteen places in Great Britain ranging from Perth to Buckinghamshire, the largest find being on the Liverpool corporation estate at Lake Vyrnwy in Wales. Out of 4309 voles examined up to the outbreak of the war in 1939, lesions of naturally acquired tuberculosis were found in 882. Cases were also discovered in bank voles, shrews, and wood mice

Macroscopically two types of the disease have been recognised—one a lymph-gland type in which the glands draining the intestine are most commonly affected; the other an infiltration of the subcutaneous tissues with a white gritty chalk-like substance containing enormous numbers of bacilli and superficially resembling rat leprosy. In both types the infection may spread to internal organs, usually the lungs in the first type and the liver and spleen in the second. Comparatively few of the animals were trapped alive, but there seems to be good reason for believing that the disease is very chronic. The route of the infection appears to be intestinal, either from soiled food or the eating of infected corpses, for the vole is a pugnacious little animal and has no nice feelings about cannibalism. WELLS has come to the conclusion that the vole acid-fast bacillus is a new strain of *Mycobacterium tuberculosis* for which he suggests the name "murine type." A vole-bacillus tuberculin can be prepared, and when the Wilson absorption method of agglutination is applied the bacillus yields serological results indistinguishable from those of the human and bovine strains The micro-organism is feebly pathogenic to the guineapig and rabbit but not to the fowl. Lastly, in fulfilment of KOCH's postulates, the culture produces characteristic lesions when injected experimentally into various types of vole.

The tissue reactions to experimental infection with this murine type of organism are discussed in the memorandum by ROBB-SMITH. In the vole itself th reaction is necrotic and histiocytic with a tendenc to calcification and the formation of minute calcareou bodies similar to those occasionally seen in the chronic tuberculosis of man. The number of bacilli found in the lesions is very large whereas the amount of fibrosis is small. This disproportion between the lesion and the number of bacilli is as striking, with the murine type of infection as it is with the other mammalian strains in the experimental lesions of the muridæ. In guineapigs necrosis is a prominent feature, while in the rabbit there is a localised cellular reaction with caseation and necrosis comparable with that observed in infections with bovine strain. On the other side of the picture, when the vole is inoculated with the bovine and human strains a typical cellular reaction with true epithelioid giant-cell systems or necrosis follows. One of the most interesting results, however, is the production in the guineapig of a chronic localised fibro-epithelioid reaction with caseation, suggestive of the tuberculous lesion seen in man. This was achieved by a preliminary infection with the murine strain followed by a bovine-strain inoculation

In studying the various cultures of vole bacillus isolated, WELLS notes that "G" strains, isolated from voles in Greskine Forest, Dumfriesshire, differ from other vole-bacillus strains in cultural reactions and in possessing greater virulence. In this issue Dr. YOUNG and Dr. PATERSON report some experiments made with a freshly isolated culture of a G strain (i.e., 564) which proved in their hands to be more virulent than others isolated. Using it for vaccine purposes they encountered untoward results in calves, which were confirmed in laboratory animals. This finding is reminiscent of the earlier experiments with the Calmette bacillus

The isolation of a new strain of *Myc. tuberculosis* has naturally opened up the possibility of a new prophylactic vaccine on the lines of B.C.G. WELLS, BIRKHAUG, and others have already made experiments to this end, both on animals and on man, and some broad facts have been established. In the first place neither the vole bacillus nor B.C.G. vaccine conferred immunity on the guineapig. Perhaps this is hardly surprising, for the guineapig's resistance to tuberculosis is so feeble that no vaccine has yet succeeded in giving it really adequate protection against even small-dose experimental infection; and literally thousands of attempts have been made Tests made with cattle by GRIFFITH and DALLING in the early stages of the war were, however, more encouraging—better indeed than with B.C.G. Preliminary tests have also been made by WELLS on man These were designed solely to determine the conditions for safe administration, and the nature of the local reaction to the vaccine. They produced results which followed fairly closely those of B.C.G. Thus of a group of 48 tuberculin-negative persons in two institutions inoculated subcutaneously, 43 developed ulcers and 2 local abscesses at the site of inoculation—a result similar to that of B.C.G. inoculation. When this route of vaccination was abandoned in favour of the modern multiple-puncture method, in 69 tuberculin-negative persons there was no general reaction, no ulcer formation, and only a series of raised papules which persisted for some weeks and then faded. Tuberculin reactions became positive. No claim is

2. Wells, A. Q., Robb-Smith, A. H. T. The Murine Type of Tubercle Bacillus. *Spec. Rep. Ser. med. Res. Coun., Lond.* no. 259, 1947.

made that vole-bacillus vaccine produces resistance to tuberculosis in man; this can be determined only by long and patient trial, as in B.C.G. But there is some evidence that it retards disease in guineapigs and in cattle.

Naturally the question of stability of virulence of the organism has been raised, as it always should be when living-culture vaccines are used; it will be remembered that this subject created a good deal of controversy some years ago in the case of B.C.G. With the vole bacillus the issue is different. Although the early history of Calmette's bacillus is not as detailed as we should like, bacteriological records show that it was originally fully virulent and that it became avirulent through long years of subculture. The vole acid-fast bacillus on the other hand is a new strain, which, with the exception of the G culture variant, starts its laboratory history with a record of feeble virulence. Young and Paterson take the conservative line that no strain of acid-fast bacilli should be used as a living vaccine in man before exhaustive tests have been made to determine the highest virulence which it is capable of attaining, and they suggest a minimum period of three years' observation for this purpose. They also stress the importance of using only young cultures as a means of controlling virulence. It should be noted, however, that the G strain with which they obtained untoward results in animals was used along with others in the preparation of the vaccine employed by Wells in his tests on 121 persons (some of whom were inoculated more than five years ago), and that none of these persons have shown any signs of generalised infection. Nevertheless, as a precautionary measure, this particular strain was discarded in vaccination preparation three years ago. The guide to safety in all this work on the preparation of living-culture vaccines appears to be, as Jensen pointed out, the most careful standardisation of culture technique.

"Patent" Medicine Trade

The council of the Pharmaceutical Society are making a determined attempt to bring the sale and advertisement of proprietary medicines under stricter Government control.[1] In a 14,000-word report to the Ministry of Health, based on a five years' inquiry, they show that the position is now little better than it was when the Select Committee on Patent Medicines reported in 1914.[2] "Throughout the pages of most newspapers and periodicals in general circulation," says the society, "sufferers from all manner of diseases and ailments are offered beans, tablets, wines, powders, salts, pills, ointments, tonics, hormones, glands, and vaccines that will bring them youth, health, charm, slimness, strong nerves, inner cleanliness, lively livers, freedom from pain, increased (or decreased) weight, iron for the blood, purer blood, vitamins, contentment, resolution, immunisation, vitality, and so on. The advertisers' claims are frequently so fantastic that one would not be surprised to find them offering secure jobs and large salaries into the bargain." Obviously these accusations are directed against only one section of the proprietary medicine trade, but it is a large one. The report maintains that the advertisements of these firms are grossly exaggerated and often based on fraudulent claims[3]; they further the view that ill health is a normal human condition and so encourage self-medication; they lead the public to cover up their symptoms instead of seeking skilled advice, so prejudicing the success of treatment; they create an atmosphere of fear, whether of ill health, operation, premature old age, or incurable disease; they undermine public confidence in a State medical service and the doctors who will provide it; they extract excessive fees from the sick; and they use scientific terms to impress or deceive the uneducated and credulous.

Experience of National Health Insurance suggests that, far from reducing the demand for self-medicaments, the coming National Health Service may even increase it; the sales of proprietary remedies doubled in ten years after the introduction of N.H.I. The self-treatment habit is already deeply ingrained, and the society fears that the new service may usher in a golden age for "commercialised charlatanism."

How can the public be protected against the unscrupulous salesmen who exploit their ignorance? It has not been enough for newspapers to adopt a voluntary censorship, for claims to cure certain diseases to be banned, or for the contents of each bottle to be compulsorily disclosed. The Ministry of Health and the B.B.C. have taught people a little about the fundaments of health: but they have to contend against posters and other advertisements whose aim often is to perpetuate error. The only hope of stamping out a growing evil seems to lie in firm supervision of the trade itself. The society would make it a statutory duty of the Ministry of Health, with an advisory committee of doctors, pharmacists, &c., to maintain proper standards for proprietary medicines and their advertisements, and would prohibit the sale of any medicines which did not attain a place on the Ministry's register. If effective such legislation would put some medicine traders out of business; and so much capital, both in money and in brains, is involved that they will not go down without a fight. The support of the public is a first essential of success, so Government action should be preceded by an energetic campaign to show the public where its true interest lies.

Gowland Hopkins

The early organic chemists worked on natural substances; but their successors, in learning the art of synthesis, entered a new world composed of molecules made by themselves. Frederick Gowland Hopkins, whose obituary we publish this week, re-established biochemistry as a study of life—of vital processes. He urged the organic chemist to "get into touch with the animal," whose body "usually does the unexpected"; and he saw biochemistry as a borderland science, fit meeting-ground for many minds. "It is never," he said, "out of place to urge that the living cell should be thought of as a dynamic, and not a static, system," and to this new dynamic biochemistry he made great contributions both by experiment and by quiet leadership. Long ago E. H. Starling spoke truly of his power of "finding among the thickets of ignorance which surround us some path to knowledge which others had passed by unheedingly." His life was one for which we may all be grateful.

ECOLOGY AT CAMBRIDGE

Cambridge University plans to establish a department of human ecology. By dictionary definition this subject covers the study of the whole of man's habits and modes of life, and his relations with his surroundings: but the faculty board have wisely mapped out a more limited territory for initial exploration. Some special opportunities are offered by East Anglia, which has both urban and rural populations and where some of the isolated villages of the Isle of Ely are almost closed communities, ideal for studies on epidemiology, hereditary factors in disease, and the effects of a fixed environment on susceptibility. In addition, the Fens provide plenty of rheumatism. Early investigations will include one into subclinical disease and carrier-states in closed communities, confined at first to those of streptococcal origin; the new department will carry out the clinical and epidemiological inquiries, while the bacteriology is undertaken by the Public Health Laboratory Service, which works in close association with the university department of pathology, and is equipped to identify fully the different types of streptococci. A clinical and anatomical survey of rheumatic conditions, which have long been suspected of a streptococcal element, is also planned.

One function of the department will be to share in founding a new university health service, designed not only for the individual benefit of undergraduates but also to discover defects and disorders before they reach a stage which might be harmful to the community. A pilot survey, carried out in Downing College in 1946, demonstrated clearly the need for such a service: of the 214 volunteers examined by the department of medicine and the county tuberculosis officer, 1 had active open pulmonary tuberculosis, of which he was unaware, and 1 had closed non-infective tuberculosis, which was advancing. The university department of experimental psychology could also contribute to the health service. An important part of this service will be the study of special risks run by technical staff in the university—for example, from ionising radiations. The ecologists will also naturally work with other university groups, investigating such subjects as the process of ageing, and the effects of climate on health.

The new department will develop as part of the department of medicine, until the moment comes to give it autonomy under a professor. It will be staffed at first with a reader assisted by two juniors; while the university health service is to have one senior and one junior medical officer, a chest radiologist, a statistician, and necessary secretarial assistants.

SALMONELLA IN THE HOME

INFECTION with organisms of the salmonella group is widespread; and it is generally assumed that outbreaks are caused by food contaminated directly or indirectly from an animal. In this country rats, mice, pigs, and cows are often infected, while inadequately cooked duck eggs cause numerous infections with *S. typhi-murium* or *S. enteritidis*. In the United States domestic fowls and turkeys are said to be the main reservoir for salmonella but there is less evidence that this is so here. *S. pullorum* and *S. gallinarum* rarely attack humans but do take toll of our hens, and *S. thompson* causes trouble among incubated eggs and in young chicks. Until 1942 almost all strains of salmonella isolated in this country belonged to one of fourteen native types, but with the arrival of American spray-dried egg the picture changed.[1] There is still doubt about the method by which the egg and the dried product become contaminated, and while infection can take place in the oviduct it seems likely that salmonella are often sucked through the shell from moist fæc as the egg cools.[2] Whatever the mechanism, it is clear that at least ten new types of salmonella were imported into the country along with the dried egg, and outbreaks of infection with such organisms as *S. oranienburg* were fairly common. As dried egg became scarce, so the American types of salmonella infection became rare and we seemed to be reverting to the home-grown varieties. Whether a further increase in the use of the newer dried-egg powder would again bring migrant salmonella we do not know, though it is likely that the product still carries its pathogens. It may also be that such organisms as *S. oranienburg* or *S. montevideo* have already found accommodating human or animal hosts and have taken permanent abode with us.

There is still much to learn about the ecology of the salmonellas, both home-bred and imported, and collaboration between medical and veterinary bacteriologists is needed. From time to time there are reports of salmonella infection in dogs and cats, and the daily press lately described an outbreak caused by the activities of a hospital cat. We do not know very much about the part played by cats and dogs in the spread of several other types of human illness, and when the source of sporadic infection is in doubt it may occasionally be worth interviewing these dumb but socially active members of the family. The risk of introducing salmonella infections into the house in the form of a "virus" intended to destroy rats or mice is sufficiently illustrated by the paper we publish this week.

TOO MUCH HEPARIN IN THE BLOOD

IT is well known that a serious overdose of X-ray or other radiation to the whole body, including exposure to atom-bomb radiation, is liable to cause an anæmic syndrome of which bleeding from mucous membranes is a striking and troublesome symptom; it often heralds the failure of treatment, when further internal hæmorrhages are found at necropsy. A similar syndrome follows overdosage with drugs that cause toxic depression of hæmopoiesis, such as gold. The blood-platelet count is strikingly reduced in these patients and it is usual to attribute the hæmorrhage to this thrombocytopenia. Allen and Jacobson[3] now suggest that the true explanation is the presence in the blood of an anticoagulant that they identified as heparin; there is, in fact, a hyperheparinæmia. Normally only a minute quantity of heparin is present in the blood, but the great increase in coagulation-time seen in anaphylaxis and peptone shock has been shown to be due to liberation of heparin from the liver into the general circulation.

Allen and Jacobson noted that reports of acute exposure of the whole body to ionising radiation mentioned not only thrombocytopenia but sometimes also a prolonged clotting-time of the blood. They therefore tried to reproduce the effect by exposing the whole body of dogs to a single dose of 450r of X radiation. About a week after exposure the animals develop a well-marked thrombocytopenia and the clotting-time of their blood is greatly increased—in fact, the blood may be almost incoagulable. It was found that the blood of such a dog would delay the clotting-time of normal blood, suggesting that an anticoagulant substance was present. Specific anti-heparin substances, such as toluidine blue, rendered the clotting-time normal again, both in the test-tube and when given in vivo in a dose of 1·5–3·0 mg. per kg. body-weight intravenously; and bleeding was controlled without the platelet count being affected. Finally, they isolated an anticoagulant substance from this blood and found that its anticoagulant potency, weight for weight, was about the same as the standard heparin salt; it was inactivated by toluidine blue and was heat-stable.

---

[1] Topley, W. W. C., Wilson, G. S. Principles of Bacteriology and Immunity, London, 1946 vol. II, p. 1596.

[2] Haines, R. B., Moran, T. J. Hyg., Camb 1940, 40, 453

[3] Allen, J. G., Jacobson, L. O. Science, 1947, 105, 388.

The conclusion drawn from these observations is that excessive heparin in the blood is the cause of hæmorrhage in these cases. Vitamin K, ascorbic acid, calcium, and even fresh-blood transfusions are without effect on the bleeding once it has started, though toluidine blue successfully stops it. Allen and Jacobson are trying the effect of toluidine blue in other human hæmorrhagic disorders and have obtained some temporary relief. But the dose must be nicely balanced, because, although in low concentrations toluidine blue has an anti-heparin effect, in higher concentrations it acts as an anticoagulant and would therefore add to the patient's troubles.

B.A.L. IN GOLD-POISONING

THE brilliant work of Peters and his co-workers[1] during the war led to the development of B.A.L. (British anti-lewisite or 2,3-dimercaptopropanol) as an effective antidote to arsenical poisoning, especially that caused by lewisite. Recently B.A.L. has been used with some success in the treatment of arsenical poisoning arising during the treatment of syphilis.[2] The use of B.A.L. for eliminating mercury,[3] zinc,[4] and copper[5] from the tissues indicated that it might be of value in the treatment of toxic reactions after gold therapy. The treatment of gold-poisoning with B.A.L. has now been reported,[6 7 8] and although only 12 cases are mentioned favourable results were observed in all but one of the patients given B.A.L.

It is thought that B.A.L. acts by reactivating sulphhydryl enzyme systems poisoned by heavy metals. Ragan and Boots[7] observed an increased urinary excretion of gold in all their 5 patients treated with B.A.L. for gold dermatitis. Presumably B.A.L. caused the gold to be released or "washed out" from the tissues. Since arthritic symptoms returned shortly after B.A.L. therapy, Ragan and Boots suggest that the therapeutic activity of gold may be explained by temporary suppression of the processes causing activity in rheumatoid arthritis. The high relapse-rate observed[9] after gold therapy in arthritic subjects appears to support this hypothesis.

Gold is undoubtedly of value in the treatment of rheumatoid arthritis, and the possession of an effective antidote to its toxic effects would be a major therapeutic advance. However, B.A.L. may prove to be a mixed blessing, since Cohen et al.[6] have noted toxic symptoms after its use, including pains in legs, arms, abdomen, and head, nausea, vomiting, salivation, lacrimation, and perspiration. But the development of less toxic derivatives, such as B.A.L.-intrav (O-glucoside of dithioglycerol)[10] may reduce the undesirable effects. Prophylactic administration of B.A.L. during gold therapy might be of value. Very small amounts would be advisable, because the optimum concentration of gold in the tissues for anti-arthritic activity might be reduced by the washing-out action of B.A.L. already mentioned. Meanwhile, large-scale studies of the effect of B.A.L. on gold therapy are required, care being taken not to attribute to B.A.L. the spontaneous remission of toxic signs and symptoms which often follows simple removal of any toxic substance. If B.A.L. proves valuable in this way, its benefits must not encourage the slipshod or excessive use of gold.

OIL AS A VEHICLE FOR LOCAL ANÆSTHETICS

FOR some twenty years drugs have been injected in oily solution as a method of prolonging their action for days or weeks, the assumption being that a fat-soluble drug is released and absorbed more slowly from an oily than a watery solution. The manufacturers have issued various drugs in this form. Among the first to be used were oily solutions of local anæsthetics, recommended for the treatment of such conditions as anal fissure and pruritus.[1] Later other drugs such as insulin, adrenaline, desoxycortone, œstrin, stilbœstrol, histamine, various metallic salts, and penicillin were prepared in oily vehicles.

There can be no question that the action of some drugs can be prolonged in this way—penicillin is a familiar example—but doubt has arisen as to the part played by the oily vehicle in local anæsthesia. Protracted anæsthesia following the injection of such oily preparations has in some cases been shown to be due to degeneration of the nerve, the duration of anæsthesia being the time taken for regeneration. On this view the gradual release of the drug from the oil is an insignificant factor. Duncan and Jarvis[2] attribute the nerve degeneration to the presence of benzyl alcohol in the solution. In their experiments they were unable to prolong anæsthesia by the use of the oily vehicle alone. Even benzyl alcohol will not produce degeneration if its concentration is below 10%, and such solutions are probably of little value for, say, fissure in ano.

Dr. Kelly, in his paper in this issue, goes further and throws doubt on the efficacy of oil as a vehicle for any drug. His observations deserve the attention of clinicians, for it may be that, through error in observation or a disinclination to oppose accepted beliefs, we have been deluding ourselves, if not our patients, about the efficacy and mode of action of some oily solutions.

SPREAD OF PART-TIME NURSING

THE proof offered by Gloucestershire[3] that part-time nursing can be made to work, and work well, should be followed by rapid development of part-time schemes elsewhere, especially for the care of the chronic sick. Unfortunately many authorities seem backward in overcoming difficulties. No doubt these are often considerable: sometimes the geography of an area is awkward; sometimes the distribution of population is such that transport of part-time workers is expensive; sometimes prejudiced matrons oppose the idea; sometimes the officers given the task of organising the scheme are half-hearted and apathetic; sometimes an energetic and capable officer finds that his council themselves present problems. Far-sighted authorities, however, now recognise that, unless our health service is to break down completely, part-time nursing in long-stay hospitals must become general and honoured. In no other way is it now possible to provide good—or even adequate—care for the aged sick.

The Wiltshire County Council, facing the difficulties in a practical and determined spirit, have just launched a very good scheme, closely modelled on the Gloucestershire pattern. There are seven infirmaries for nursing the aged and chronic sick in the county—at Amesbury, Chippenham, Warminster, Salisbury, Devizes, Trowbridge, and Swindon. Children's nurseries are attached to the infirmaries at St. James's Home at Devizes and at Swindon. All these institutions need part-time nurses; between them they have beds for 269 men and 250 women, and are supposed to carry an establishment of 126 full-time resident nurses. When the scheme was launched, on

2. Duncan, D., Jarvis, W. H. *Anesthesiology*, 1943, 4, 465.
3. *Lancet*, March 8, pp. 294 and 300.

April 18, there were only 45 permanent staff in the hospitals, including nurses supplied by cooperative agencies. Within a month from that date the staff had been augmented by 31 part-timers—a fair beginning.

As in Gloucestershire the four-hourly shift is the usual unit of duty—from 8 A.M. to NOON, from NOON to 4 P.M., or from 4 to 8 P.M. Night duty, for those who wish to undertake it, is from 8 P.M. to 8 A.M., with two hours off duty. Some of the matrons have found it difficult to use recruits who were not able to fit in with one of the formal shifts, and this seems a pity, since Gloucestershire has shown that such casual workers can be useful as relief nurses, and that once they have formed an attachment to a hospital and its patients they will often rearrange their lives to fit in with accepted shifts. The Gloucestershire rates of pay—2*s.* 6*d.* an hour for a State-registered nurse, 2*s.* for an enrolled assistant nurse, 1*s.* 9*d.* for a nursing attendant, and 1*s.* 6*d.* for a nursing orderly—have been adopted, and transport is provided when necessary. Meals are not quite so well arranged as in Gloucestershire: one light meal is available during each shift, but while some infirmaries provide this free of charge, others charge canteen prices. It seems most undesirable that a charge should be made: rates offered to part-time nurses—even these rates, which in some respects improve on the Rushcliffe scale—are not attractive unless they carry good amenities. Leave and sick-pay are given on the liberal Gloucestershire plan; new uniforms have been ordered, and in the meantime appropriate white uniforms are lent and laundered. The scheme already shows good prospects of success: at the Lodge, Semington—the Trowbridge infirmary—a fully cooperative matron is finding her part-time recruits a welcome addition to her staff, and confirms previous experience that part-time nursing attracts a good type of woman. She points out that adequate staffing will make it possible to do much more for the patients, many of whom are more feeble and rheumatic than gravely ill; and she looks forward to the change from listlessness to active and hopeful interest among the old people, which is one of the most striking results of a successful part-time scheme.

CALORIE INTAKE IN HOT PLACES

Do we need less food in warm weather and hot climates than in cold? Most of us would say that we do, though if pressed we should have difficulty in finding actual observations to support our belief. From such authorities as Mottram,[1] DuBois,[2] and Leitch[3] it seems that the need for calories is possibly a little higher in very cold climates but not much different in very hot climates; the whole difference is anyway said to be small. The few quantitative observations relate to measurements of the basal metabolic rate, which might differ, between very cold and very hot climates, by at most about 20%, which is only about 400 calories daily.

To this we may now add a much more direct series of data collected by Johnson and Kark[4] on the average calorie intakes of troops of the United States and Canadian armies, located in temperate, desert, mountain, jungle, arctic, and subarctic areas of three continents. The writers compare the average daily intake of food of similar groups of soldiers, all healthy and physically fit, performing the same duties and all able to have as much food of a wide variety as they wished. A graph of calorie intake and local mean temperature shows that there was a close linear relationship between these two factors, from 3100 calories consumed daily at 92°F to 4900 calories at −30°F. This is a considerable difference and no doubt greater than many of us would have expected. It seems that we have not made sufficient allowance for the effect of climate when drawing up standards of dietary requirements. On the other hand, the observation that the greater calorie intakes in the colder climates were associated with the consumption of an increased proportion of fat was not unexpected.

It is not easy to explain this large effect of environment on calorie intake. It is not to be explained by differences in the B.M.R. It is possible that some, if not all, of the high intake at low temperatures can be explained by a greater heat production needed to maintain the body temperature, and the increased exertion necessitated by wearing and working with heavy and clumsy clothes and equipment.

COSMIC RADIATION AND CANCER

THE discovery that the cosmos contributes to what physicists called "spontaneous ionisation" was of great interest, not because of its magnitude but rather because of the questions it raised. Where does this very very feeble ionising radiation come from? The subject is still in dispute, but inevitably, after Muller had shown that mutations could be produced by very small quantities of X rays, it has been asked whether cosmic radiation has any effect on biological processes. Figge[1] has now tried to find out whether cosmic rays have any effect on the production of cancer. He had to use an indirect method, because to shield an enclosure from cosmic rays would require a lead roof 50 feet thick. He arranged for one batch of mice, housed normally, to act as controls to another batch kept in cages with lead covers whose function was to increase the normal cosmic radiation by producing what have been called "cosmic-ray showers." The mice were all injected with 0·25 mg. of the carcinogen methylcholanthrene in sesame oil. The mice were kept under observation for five months and the appearance of tumours noted. Figge says that "the rate of induction of cancer in the mice kept under the lead plates was found to be consistently and definitely higher than in the controls." The experimental data are few on which to draw definite conclusions—thus there are no data on the relative degrees of ionisation in the whole group of cages, the total of 184 mice is not enough to allow one to estimate accurate quantitative differences in tumour appearances, and it may be that environmental factors have not been given due consideration. Experiments are now being planned on a bigger scale.

BLOOD TEST FOR MUMPS

IT has been known for some years that the blood of patients with mumps commonly contains an increased amount of amylase, and this has been used as a test for the infection. Wolman and his colleagues[2] in New York have applied the test to 101 men in hospital with mumps and 47 healthy controls. They find that the serum amylase is nearly always raised in the first week of the illness and the increase usually then fades away. The test seems reliable enough to be useful in doubtful cases of swelling round the jaw. The salivary amylase is usually low in mumps, so it seems that the enzyme from the inflamed parotids leaks into the blood instead of reaching the mouth. This view is supported by the observation that there is no rise in serum amylase when mumps is confined to the submaxillary or sublingual salivary glands; neither is there a secondary rise when the testicles become involved when the parotids are subsiding.

Reconstruction

THE VICIOUS CIRCLE OF AUSTERITY

Adjusting Our Food Habits

F. Le Gros Clark
M.A. Oxfd

A moment may be reached, for a man or even for a whole community, when austerity can no longer be reated as a temporary expedient. It has become the normal state of existence. Have we in Britain now reached that stage in respect of our daily diet? For if we have, we had better not delay the process of adjustment. We are at present existing on a kind of patchwork diet composed of all we can manage to retain from our pre-war pattern of food habits. The diet as a whole may or may not be physiologically adequate; but there is not enough of any of the foods upon which we set a raditional value. We do not dare to be open-handed with ourselves, and, what is worse, we dare not be hospitable in the old way.

We are warned that this may continue for a further three years or more. But even then, to what can we look forward? Rationing will have lasted almost half a life-time for many of our young adults. Should we not, therefore, renounce the old pre-war pattern of diet and begin to work our way towards a new tradition of national dishes and meal customs? Our first task is clearly to consider not the kinds of food we should prefer to eat but the kinds of food we are likely to acquire.

SUPPLY—

By the coming harvest we may have enough bread grains, though of this there is no certainty. But the end of bread-rationing, while it will come as a relief, will not restore the sense of sufficiency. So far as other foods are concerned, we must not forget that there is a slow shift at work in the world markets, upon which we have to depend for more than 90% of our fats, 75% of our sugar, and more than half our meat. The Scandinavian markets are showing a slight tendency to move to the eastern countries of Europe, from which supplies of coal and later of useful manufactured goods may be expected. South America is becoming industrialised, and no-one would care to predict when and under what conditions the Far Eastern markets for rice and vegetable oils are likely to be re-established.

—AND DEMAND

Our potential demand for food has also increased and may increase considerably above the pre-war level. Not only do we have a larger population than we had in 1939, with a larger proportion of adult consumers, but there is an increased demand for various foods, sustained on a high level of employment, a tolerable level of wages, and a subsidised food market. If we allow for all these factors, we may well suppose that in a completely freed market, provided that prices are kept stable, the total demand for meat, fats, fruit, and bacon would rise by 20% above the pre-war level. The demand for sugar might rise by anything from 10 to 15%. As for milk, we have not only allotted a fair proportion of it to our special classes of consumers but we are looking forward to an expansion of the milk services, and at the same time we are fostering a taste for milk that is pressing heavily upon the supply. In brief, if we aim at restoring the pre-war pattern of the British diet, we shall have somehow to acquire far larger supplies of many kinds of food than we secured in the thirties.

We could of course remove the subsidies, which are now approaching £400 million a year. Retail prices would rise and food consumption would be curtailed, at all events in some commodities. But low food prices have now become part of the economy of the country, and any attempt to shift the structure would lead to unpredictable consequences, not only for nutrition but in the industrial field. The Government does not appear to meditate such a step with any conviction. The use of subsidies implies control, and yet there seems no prospect that a fall in the price of food will enable us to dispense with subsidies for an indefinite time ahead. In that case the stability of prices means a very large potential demand, and that, if we are to have a fair distribution of the foods in short supply, involves us in continued rationing.

CHANGING THE PATTERN

There is only one way by which we can break the vicious circle—by cutting at the very roots of our traditional diet, of which our present dietetic pattern is a faint and unconvincing reflection. We have assumed since 1939 that the time would come when our pre-war habit of eating, or the habit we should have adopted if we could afford it, would be restored to us. Should we now relinquish our wearisome attempt to live on a diet of shreds and patches and cultivate a taste for a simple and wholesome basic diet, to which variety could be added as the means become available?

This reads as though it were a plea for the simple peasant diet; but it is of course nothing of the kind. It merely implies that if we have to rehabilitate our economic structure on a system of rigid priorities, and that, I suppose, is fairly evident, then we had better begin by establishing a scheme of priorities in the complex food market. It is surely preferable to plan for a few basic foods to be in full supply as soon as practicable than to subsist on a diet that has to be precariously balanced from period to period.

We have made a good start with the ground-nut scheme in East Africa. It seems improbable that Asia will remain a source of exported vegetable oils. We might further examine what land in Africa could be opened up for the production of feed grains, some sugar, and of tropical fruits. In home farming it seems to me advisable to embark on a policy of expanding milk production and the production of high-quality feeding-stuffs. The residue from oil-bearing plants may soon no longer be exported to this country as cattle-feed and ultimately as manure. It may be used in its country of origin to maintain herds and soil fertility. If we are to become one of the great milk-producing countries, we may consider the advantage of processing the surplus into cheese and dried milk. Milk is the least wasteful of animal products as a mode of converting vegetable foods into animal protein. Moreover, its uses are very varied.

We could, in other words, let meat and butter take their chance on the import market, and breed for milk and cheese. I do not suggest that this is the only solution but it is probably the surest.

Our main fats would in that case, of course, be derived from imported vegetable oils, no doubt at a later stage processed in the countries of origin. Meat would have to be imported as and when we could procure it; but the milk herds will yield fair quantities of beef as a secondary product. If we get about 75% imported wheat and the same proportion of imported sugar, the rest lies with potatoes and with a scientific research into the market for home-grown vegetables. It is time that such a research was begun.

THE CONSUMER

Our basic diet will have to be adapted to the kinds of food that we can make available, and that will be a problem in adjustment, for which we have few precedents. We are dealing with the food of a people, who are not only themselves mainly urbanised and have had for a century and a half ample supplies of coal for cooking but who have subsisted increasingly over the last two centuries on cheap supplies of imported sugar, wheat, spices, dried fruits, bacon, and meat. The typical peasant fare, on the other hand, is represented by the rice bowl in the East and the stew pot or pot-au-feu with hunks of bread in Europe. This is a basic meal form which is far easier to deal with, when superficial adjustments have to be made. Provided the foundation of the dish is accessible in the shape of rice, potatoes, meal, or cabbage, its other ingredients may be varied to almost any extent. The dish is in any case a composite one, and where he cannot add to it small quantities of meat or fish, beans or bacon, the primitive consumer resigns himself to the basic ingredients.

SUMMARY

We need a food plan, and the essence of our plan must be to decide upon what foods we intend to concentrate in a convinced effort to bring them into full supply. The decision will have to be reached through the adjustment of our dietetic needs to our chance of obtaining the necessary supplies. We are living in a world that is in process of change; and it is not safe to assume that the world markets will resume their pre-war structure. We should play for security. I have suggested one possible line of solution, and no doubt there are others. In effect, we should attempt in the next ten years or so to become a milk and cheese producing and consuming country and enlarge our sources of vegetable oils, feeding-stuffs, and sugar on the African continent. Meat, bacon, butter, and a few other traditional foods might have to remain on ration indefinitely if they are to be fairly distributed, but the quantities on ration would depend on supplies from period to period.

As for the public, it would have to be persuaded to barter its uneasy dream of a return to its pre-war food pattern for a plan and an enterprise. Perhaps there is after all one remote precedent for such a choice—the fleshpots of Egypt were set long ago against the vision of a land flowing with milk and honey.

BURSARIES FOR FUTURE HOSPITAL OFFICERS

To encourage recruitment of suitable personnel, King Edward's Hospital Fund for London is offering bursaries for those seeking training as hospital administrators, domestic supervisors and welfare officers, and caterers.

Hospital administration.—Six bursaries are to be awarded this summer. There will be (1) three junior bursaries, of the value of £350 a year, for men or women aged 20 to 30; and (2) three senior bursaries, without a rigid age-limit, and with a salary of £600 a year. The courses will provide for 18 months' training in three different hospitals, and holders will normally be expected to sit the examinations set by the Institute of Hospital Administrators.

Domestic administration.—Six bursars are to be appointed, at a salary of £250 a year, exclusive of board and lodging. The training course, of one year, will be divided into three terms, spent in three hospitals. Candidates should be women of good educational standard; it is desirable that they should be experienced in personnel management or welfare work, in institutional management or domestic science, and in other administrative work.

Catering.—Eight bursaries are to be offered, each with a value of £300–£600 a year, to prospective catering officers. Bursars will be appointed to one or other of the London hospitals for a 12-months course. Knowledge of catering, nutrition, institutional management, and administrative work will be taken into account when the appointments are made. In 1943 the Fund published its first Memorandum on Hospital Diet,[1] in which it was suggested that while hospitals had, by the appointment of dietetic experts, applied modern principles of nutrition to special diets, they had not in the past applied these principles to general-ward diets; catering, it was proposed, should be in the hands of one responsible catering officer. The recommendations have been widely adopted, and there is now a large demand for caterers and dietitians.

Applications should be addressed to the secretary of the Fund, at 10, Old Jewry, London, E.C.2.

In England Now

A Running Commentary by Peripatetic Correspondents

THE toddlers' clinic had thrown up an evil-looking small boy with a permanent scowl, who made a habit of pouring bottles of lighter-fuel into gas-fires. I made a diagnosis of original sin, but felt guilty about it, and when I met my tame psychiatrist I confessed. He became really expansive, and suggested that anyone who talked of naughtiness should be off the Register—the child's sexuality was obviously fixed in some organ other than the usual one. I asked him what one did about it, and whether it couldn't be persuaded to move on. He was rather less happy at that, and said that it all depended, and why didn't I test him, and see what his constitutional type was? I left with a book, ready to meet the scowling child on equal terms.

Among the tests in the book I felt rather like Alice in Wonderland, and decided that the delinquent child had better have a bite out of the nearest psychological mushroom—at least I could score him on one of the less ferocious quiz-papers and work out the details of his sexuality when there was a lull. He looked as if one might be able to time his reactions if not predict them. "Now I want you to say the first word that comes into your head when you hear me say each of these words—as quickly as you can." The scowl deepened. "Dog," I said hopefully. The child dug in a pocket and transferred something to his mouth. After a full half minute he ceased to scowl, and remarked "We got a dog." Then he began to chew. The outlook was unpromising. We met with less success with the blots of ink which filled the latter half of the book. After distinct signs of inhibition and non-coöperation had appeared, and the bottle of acetone for patch-tests had gone for six (whereupon the scowl changed to a guffaw), I wrote a note to the child-guidance clinic and advised that an exploratory use of the slipper might move the sexuality back again if one found the right spot, and waited for somebody to tell the G.M.C. about me.

When the door closed I had another go at the book of tests, to see where I had failed. Another quiz met my eye: "Do you frequently have the feeling that you cannot cope with your work?" Yes, frequently. "Do you feel that the top of your head is compressed by a weight?" Less often than in former times, but still sometimes. "Do you often feel that other people hold foolish and mistaken views on important questions?" You bet. "Have you ever had a vision?" Not yet. But I might, at any moment now. When I added up my total I realised why I could never cope with child delinquents—I belonged to all the possible reaction-types. I could make a living by hiring myself out to the D.P.M. examiners. At the end of each questionnaire I expected to find: "If you answer yes to more than six of these questions, then Buggins's Pills will restore you to radiant health," but there was positively no advertising matter. I was booked.

My psychiatrist was apologetic. "I'm afraid I gave you the adult tests by mistake," he said. "And, of course, all these things need practice." It was only when the guidance clinic reported that I recovered my sang-froid. "This child is thoroughly out of hand. He would benefit from more discipline and a less haphazard parental attitude. I agree that when his escapades cause trouble he should be punished in moderation, but his insecurity at home would be relieved if he had more outlet for his energy—I suggest school." So did I. I am going to get my grandmother down to the clinic next week, and see if I can't get her a Diploma in Child Guidance. She is a remarkable old lady who can cope with small boys and usually knows the right place to swat their ectopic sexualities. She might even get her D.P.M. for the asking.

* * *

How many nostalgic Servicemen in convoy at the Cape have bussed to Kensington or Windermere, two juxtaposed coloured-native townships of Capetown, to return sadly and rapidly? For Windermere is, if possible, a worse slum than Kensington. Made roads are few (there is a technique of taking sandy patches fast and in second gear); one trudges through sand to a maze of tin shanties ("pondokkies") half the size of stables; jam-tin labels and pre-war coloured illustrations of motor-cars often serve as wallpaper; and pigs and chickens squabble for food between "houses." As I write, it has been hot and dry for four months, and enteric is on the increase. How distant seem thy placid waters and sweet rolling hills, O Cumberland!

HÆMATOLOGIA

Here in the file
I see the old names,
Raymond, Riley,
Robinson (James).

Raymond, Riley,
Robinson, Rudd,
Died of malignant
Disease of the blood.

Hodgkin's, leukæmia,
Carefully docketed
In the right hole
Where fate had them pocketed.

Dead with an accurate
High-power diagnosis,
Hodgkin's, leukæmia,
Myelosclerosis.

Here are the blood films,
Bone-marrow and blood,
Raymond, Riley,
Robinson, Rudd.

Raymond's a beauty,
Acute monocytic.
Remember his gums
Which were quite characteristic?

Remember his wife, too?
"He was always so strong.
Are you quite sure, doctor,
No chance of being wrong?"

Beautiful blood cells,
In all the wrong places.
"Got your powder-puff? Right.
Mustn't guess from our faces."

Robinson (James)
A straight myelosis
Had a perfect remission
That shook my prognosis.

Looked like a cure,
Really most satisfactory,
Until a relapse
Proved completely refractory.

Nitrogen mustard,
Radiophosphorus,
Some other new remedy,
What does it prosper us?

Go through the motions,
Penicillin, transfusion,
Until it's quite clear
There's but one conclusion.

Staining the blood cells
Like a technician,
Telling the relatives
Like a mortician.

Staining for granules
Or diffuse basophily,
Don't slow down to think
Or life seems too silly.

Raymond, Riley,
Robinson, Rudd,
All of them dead
Of disease of the blood.

Letters to the Editor

HOSPITAL WARD PLANNING

SIR,—The article by Dr. McIntosh and Mr. Coales in your issue of May 10 is of particular interest at a time when many of us are considering the specification of new hospitals.

Some of the ideas expressed in this article are particularly welcome; firstly the suggested ratio of single-bed wards to total beds (30% in two of the proposed plans) provides for the needs of patients who are very ill, immediately postoperative, infective, or disturbing to others; secondly the advocacy of small wards of four to eight beds; thirdly the linkage of the ward units with due regard to traffic problems; and lastly the number (but not the distribution) of the ancillary rooms.

Nevertheless there is much to criticise. Cross-ventilation is considered as an isolated function, whereas the problem of ventilation is complicated by the necessity of considering the heating of the ward unit. In practice cross-ventilation is often negatived by patients or nurses seeking comfort; consequently windows are often closed to prevent draughts or to keep the wards warm, so that in actual use the modern Continental and American approach is probably as effective as our more spartan ideals.

My main objection however is to the use of transverse corridors which necessitate nurses working out of sight of the wards. In these wards it would often take some time to locate a nurse or sister. On the other hand the Continental plan, with ample use of glass in corridors, enables the ward to be under better observation and the nurse to be nearer the patients and to reduce her walking distances.

Lastly, though I cannot speak as an architect, I suspect that the great length of the perimeter would make for expensive building, and further, that the deeply indented plan must reduce the total insulation of some of the wards, particularly if the main aspect had to face S.E. or S.W.

London, W.1. HUGH GAINSBOROUGH.

BACKACHE

SIR,—I read the article of Mr. Burns and Mr. Young (May 10) with extreme interest. For the past four years I have held the opinion that the majority of cases of low back pain are due to disk lesions and I am therefore in entire agreement with their views on the pathology of backache and sciatica. Where I disagree is with their somewhat dogmatic statement that "operation is the rational form of treatment for all cases of severe backache with disk lesion." The only alternative they offer is rest in bed for a maximum of three weeks, or a corset. The plaster jacket is dismissed in one sentence as "cumbersome and less comfortable than a corset, which is as efficient in restricting movement at the lumbosacral junction." It would appear that they have no great faith in conservative treatment.

Bed rest to be effective must be absolute, and this is seldom the case. In hospital the bedmaking routine takes place twice daily, and at home the patients get up to go to toilet. In my experience a well-moulded plaster jacket is far more effective than a corset in immobilising the lumbosacral joint, and it remains in situ for 24 hours per day and is not taken off on going to bed. It produces rapid relief of symptoms, it is comfortable and not unduly cumbersome, and a patient in a sedentary occupation can return to work wearing the plaster jacket. I am firmly convinced that immobilisation in a plaster cast for an adequate time will cure 90% of disk lesions.

Figures can be misleading. Burns and Young state that out of 248 cases of sciatica treated by them in 1939–42 and not operated upon 79% were still having symptoms in 1945. This is not altogether surprising, since at the time in question manipulation followed by vigorous exercises was the treatment in vogue and the effects of complete rest were seldom tried. My results for the same period would be equally bad, if not worse. As regards their figures for cases operated on during 1941–45, they deserve every congratulation for their brilliant results, and nobody will dispute that in their hands operation involves no risk and offers every prospect of cure. But, to my mind, there has been no control series treated by really adequate conservative measures, and I wonder just how many of their cases might have been cured by immobilisation in plaster.

During the past four years I have treated over 300 cases of disk lesion, some with only backache, some with sciatica, by immobilisation in a plaster jacket. Approximately 90% were completely relieved of their symptoms, 5% though improved had some pain, and 5% underwent laminectomy. Nowadays the 5% not wholly relieved would also have been referred to an orthopædic surgeon. I find that the great majority of patients experience rapid relief of pain following the application of the jacket. In a small minority the pain becomes worse. This I regard as a clear indication for surgical intervention and waste no further time.

Admittedly many cases in my series were diagnosed early in their first attack and treated before degeneration of the disk had occurred. A follow-up, now in progress, shows that a small number of cases have had relapses, but I am confident that the figures will be at least as good as the 80% complete cures of Burns and Young.

The only drawback to conservative treatment in a plaster jacket is the length of time the jacket must be worn—in my series an average of 9½ weeks. Patients treated lately have required a longer period of immobilisation than was formerly the case. This, and the increased incidence of the lesion I attribute, in part, to the poor quality and quantity of our protein intake.

I could not agree more with what the authors say about faulty posture, and would go further. Posture is often protective rather than faulty, and on more than one occasion in the past I have provoked an attack of sciatica by prescribing corrective exercises for severe lumbar lordosis. Like Burns and Young I have usually found epidural injection ineffective, but on occasion it may produce dramatic relief. In 1941 I failed to cure a girl of 17 with sciatica by manipulation, the treatment then in vogue. She had what I now know to be a typical disk lesion, though at the time I wrongly diagnosed it as sacro-iliac strain. In desperation I gave her a massive epidural injection with normal saline. She experienced instantaneous relief of her pain and I can only conclude that a nerve-root was adherent to the damaged disk and that the injection freed it. The patient was so impressed that she decided to become a physiotherapist! She works in a hospital which I visit and remains absolutely symptom-free.

In the future, as the "disk syndrome" becomes more generally recognised, early diagnosis should considerably reduce the incidence of chronic backache and sciatica.

London, W.1. E. J. CRISP.

SIR,—In their article of May 10, Mr. Burns and Mr. Young say in effect that nearly all recurrent attacks of backache, and nearly all cases of chronic backache, are due to disk lesions: if bone changes are excluded by routine radiography, there remain disk lesions and rarities. "We see little evidence," they observe, "of rheumatism, which is supposed to be associated with, or made worse by, cold and damp, as a cause of painful backaches."

There is a complex syndrome, which, although of highly individual form and reproduced in innumerable instances, has no accepted name. In common speech it is called "muscular rheumatism." Hundreds of thousands of people in this country know its symptoms well; and know beyond any doubt the sharp aggravation brought by certain climatic conditions, notably by cold and a *rising humidity. Its pathogeny is unknown;* but it is very possibly a disorder of skeletal muscle consequent on a disturbance of autonomic regulation, especially the regulation of the muscle's blood-supply. In an able monograph on *Neurotonia* published in 1925, Guillaume drew attention to the complaint made by many victims of autonomic instability of "pains of a neuralgic type, localised or vagrant, or of pains in the muscle masses, vague pains like the stiff tired back of chronic lumbago (*à type de courbature lombaire*)."

This type of "rheumatic backache" abounds in rheumatism clinics. If they are all disk lesions, as I take it they must be, it follows that sufferers from the common rheumatism are peculiarly liable to disk lesions—that the pathogenesis of this complex syndrome is also, in many instances, that of the morbid change in the annulus fibrosus which we must postulate to account for nuclear protrusion without antecedent trauma.

If, in their next series of proved disk lesions, Mr. Burns and Mr. Young would observe how many of these patients also suffered from a vagrant myalgia or any of the many marks of disturbed autonomic function, either coincidently with their backache or in the past, information of the highest value in the elucidation of the pathogeny of the disk lesion might be secured.

I imply no criticism of their work in suggesting that they might invite a physician to join them in these observations. Indeed, I am writing this comment on their conclusions largely because of the opportunity it gives of pleading for a close association between orthopædic centres and the rheumatic units about to be created.

London, W.1. KENNETH STONE.

SIR,—Mr. Burns and Mr. Young are to be congratulated upon their excellent article. The work done by orthopædic and neurological surgeons during recent years has thrown valuable light on this hitherto obscure subject. While applauding the conclusion that backache is mainly mechanical in origin, I doubt whether the question is as simple as they seek to make it and whether all cases of backache and sciatica of mechanical origin are due to lesions of only one—the intervertebral disk—of the many structures involved in the mechanical breakdown. In most cases the sequence of events would seem more likely to be as follows.

As a result of some strain, often quite trivial and usually when in the forward-bending position, the lumbosacral articulation becomes internally deranged. The intervertebral disk between L 5 and S 1 (as well as many other structures) is involved in this strain, but at this early stage probably not to the extent of protrusion. The acute pain, so-called lumbago, is probably due to irritation of nerve-endings in the synovial membranes of the joint and in the surrounding soft tissues. Contraction of ligaments and muscles in the area immediately causes increased pressure on the intervertebral disk. If, as generally happens, the condition is not properly diagnosed and treated, the patient walks about, thus causing an increasing and constant strain on the intervertebral disk until the nucleus pulposus eventually protrudes, as Mr. Burns and Mr. Young have shown. The time taken for this to occur depends upon the degree of injury to the posterior longitudinal ligament and the annulus fibrosus of the disk. Quite often, even without treatment, the disk never protrudes at all.

Unlike Mr. Burns and Mr. Young, osteopaths, by manipulation, get very satisfactory results in backache and early sciatica and surprisingly good results even in old-standing cases. I can only explain this by suggesting that the manipulative technique of the osteopath is superior to that of the orthopædic surgeon. Whereas orthopædic surgeons learn and perform their manipulations on anæsthetised subjects when all tissues are temporarily relieved of strain, the osteopath prefers to study the problem as it really is and develops his technique in keeping with the degree of strain of the joints and tissues. Further, while the orthopædic surgeon after he has performed his manipulation hands his patient over to the care of a physiotherapist, the osteopath himself conducts the treatment until the affected joint is completely mobilised. Considerable trouble is taken by the osteopath, not only to establish normal movement of the deranged joint but also to build up and restore posture. It is highly probable that, as a result of the patient being anæsthetised, far more force than is necessary is exerted by the orthopædic surgeon, possibly even to the extent of creating further injury.

If the disk has been allowed to protrude extensively, the protrusion is unlikely to be corrected by manipulation, but I am convinced that there is a stage in backache when the disk is either only squeezed or is so slightly protruded that it will respond completely to osteopathic manipulation. I am further convinced that if lumbago were diagnosed for what it usually is—namely, a derangement of the joints of the lumbar spine and pelvis, involving the intervertebral disk, not to the extent of protrusion —and if from the start it were efficiently treated by osteopathic manipulation, very few would develop a degree of protrusion requiring operation.

Although this end is not immediately attainable, owing to the lack of properly trained osteopathic specialists, it is encouraging that osteopathic methods are now being offered to the medical profession through postgraduate training. It can be hoped, therefore, that with enough osteopathic specialists within the medical profession, the orthopædic surgeon will be relieved of performing the number of laminectomies that are now necessary.

Finally, it must be remembered that backache is by no means confined to the lumbar region. It can occur throughout the whole spine, although naturally it is commonest in the areas under the greatest strain from the erect posture. I have no doubt that eventually the osteopathic explanation of many cases of intercostal neuralgia, brachial neuralgia, neuralgia and headache will be universally accepted.

London, W.1. GEORGE MACDONALD.

COMPENSATION FOR I.M.S.

SIR,—Officers of the Indian Medical Service faced with finding a new career can hardly be expected to look upon the proposed terms of compensation with anything but the gravest misgivings. The maximum sum is £6000 for those who were 39 years of age last birthday, which will apply to a comparatively small number of officers who joined the Service during the years immediately prior to the war.

Civil officers, as set out in table I of the white-paper,[1] are to be compensated on a years-of-service basis, and the maximum of £8000 is paid after 16 years of service. Many I.M.S. officers with similar periods of service will only draw about one-third of this amount, or less, which will be hardly sufficient to guarantee rehabilitation with reasonable freedom from want and anxiety.

SERVICE MEMBER.

SHORTAGE OF NURSES

SIR,—Your last issue contains a memorandum from hospital doctors on the nursing shortage. I entirely agree with them about the character and incidence of the shortage. I agree, too, that alternative forms of employment are easy to obtain. But nursing in itself is so fundamentally "womanly" and enjoyable that remedies can surely be found.

Propaganda of the *advantages* of nursing may well be necessary, but the main need is for a complete overhaul of nursing education. The present apprenticeship system asks for an impossibly high theoretical knowledge; bedside teaching of practical nursing scarcely exists, and training is prolonged as a form of cheap labour. Can one wonder that there is a shortage of recruits?

In my opinion the memorandum does not go far enough. Nursing education must be put on a proper footing, and should be financed by the Ministry of Education. Fees should not be charged, but the student nurse should cease to be a paid employee. She should become a bona-fide student with a maintenance grant sufficient to meet her expenses where necessary.

Also I believe the writers have somewhat mistaken the idea of the short basic course of nursing. It must be *preceded* by a well-designed preparatory course in *elementary* anatomy and physiology, and practical hygiene of a very vital type, linked to practical elementary bacteriology. Good plain cookery, service of meals, household arts and crafts, and so on, should also be taught. This course could be carried on in one of three ways—as a full-time pre-nursing course, as part of the one-day-per-week-in-school plan envisaged for girls of 15–18, or as a part-time or evening course. It should be designed to awaken an objective interest in health, and need not be confined to intending nurses.

During the basic training, which requires a full two years, only a minimum of time should be spent in instruction away from the bedside. Theory there must obviously be—but let it be designed for nurses and not a dropped-down medical curriculum. The block system is wrong in principle in that it removes the student nurse from the object of her study. The main point about this scheme is that the nurse must receive continuous bedside instruction. Ward sisters are saddled with a multitude of responsibilities, and relatively few make serious efforts to teach their art. That is why the soul is going out of nursing. The status of ward sisters must be raised. There must be more of them (and fewer beds per ward). They must have adequate assistance for their ward management, and they must then realise their teaching responsibilities. I am certain that far more teaching could be done even today, if only the existing trained nurses would make the effort.

Lastly, postgraduate training. This should be conducted by university faculties of nursing. All who show sufficient promise during their basic training should be given the financial assistance needed for entering these courses, which should be designed to give a two-year or three-year comprehensive training to equip the student for a fairly wide field of activity. Under the existing schemes, twelve years can be spent (on a pittance) in getting all-round qualification. That is nonsense.

The university schools would have power to dovetail trainings to prevent overlapping, and the necessary practical experience should be obtained only in the first-class schools of nursing and other nursing fields. The ward sister, district nurse, industrial nurse, and so on would take a two-year diploma course. A general or special nursing degree could be taken in three academic years.

To suggest university schools of nursing is not simply to put forward the average American university scheme. Most British nurses feel that our own nursing has values peculiar to itself, and we should be sorry to see any high-falutin step taken which would lessen our practical skills. Many of us feel that the new General Nursing Council's regulations, which now lie before the Minister of Health and await his signature, are fundamentally wrong. We ask with deepest sincerity that these regulations should not be signed, but should be sent back for further consideration.

The establishment of several types of experimental schools of nursing is long overdue. In our hidebound profession it is a sin to have "ideas." Nevertheless, the right staffs should be found and the schools begun.

Meanwhile, the nursing profession must tighten its belt and be determined that no more wards shall be closed. Florence Nightingale would have answered this crisis by a new call to action. MEDITRINA.

SIR,—The shortage of nurses has been discussed freely in the press by every group associated with nursing except by that most important group of nurses, the ward sisters and senior staff nurses.

To these women alone falls the responsibility for the intensely personal nursing care of the hospital patient. In a sense, therefore, all other nurses, senior and junior to them, are subservient to them in function and exist largely to maintain them at their task. In the main, ward sisters, &c., love their work and ask no other, and they not infrequently reject the opportunities of promotion and increased pay and power, mainly to administrative and teaching posts, because it means their leaving real nursing. They are in a lifelong work and know it.

It is they, too, who train the probationers at the bedside, and either teach them to get satisfaction from their work or in some cases cure them forever of the itch to nurse. It is, in fact, probably the satisfaction they themselves get from their work which makes them take little interest in things outside their wards and hospitals, so that their voice is little heard in the politics of nursing. They are liable, thus, to have change inflicted on them and their patients without their voices being heard.

Presumptuous as it is to attempt to speak for them, it must be attempted, and suggestions are offered for improving their lot and that of others.

1. *Improved living conditions.*—Their residence should be a home for them and run on club lines by a committee elected from among themselves. Control should be by the purse-strings; a matron or superintendent should seldom have to interfere, but their right to do so should be maintained.

Permission and encouragement to live out should be given.

Administrative sisters should not live in the residence, but either in hospital, a separate home, or privately.

---

[1] Cmd. 7116. H.M. Stationery Office. See *Lancet*, May 10, p. 652.

Some, certainly, will have to live in hospital. The key to the ward sister's happiness is no interference in her "home life." Thus home-sisters are not required, but non-nursing housekeepers without disciplinary powers.

2. *For all nurses.*—Reasonable care of the health of all nurses. A daily nurses' surgery; special single and double wards for sick nurses in the hospital; and a great deal more care and sympathy, from the doctors down to the sisters themselves, for any ill member of the staff, than is commonly meted out today.

Improvement in food should be arranged, but the sisters' committee should be able to speak out for them.

3. *Training of probationers* is an integral part of a ward sister's post, but there are some who cause a wastage of up to 100% of probationers under them, who leave nursing discouraged. Ward sisters should therefore be trained in (*a*) the teaching of nursing as a *practical subject, and* (*b*) *the understanding and handling* of the young nurse. Those sisters who cannot teach or handle their probationers, though otherwise good nurses, should find other tasks in nursing.

4. *Pay.*—It should be possible for a ward sister, without leaving active nursing, to reach in time, by some type of graded promotion, pay equal to that of an assistant matron.

5. *Better propaganda.*—Newspapers today stress the hardship of a nurse's life—the best way of discouraging new entrants to nursing. The compensations in the career of nursing are many, and the task of nursing itself and the community of a hospital are among them. These are not mentioned.

ROBERT PIPER
HILDA PIPER.

Gerrard's Cross, Bucks.

SIR,—Student nurses would agree with your correspondent that old-fashioned restrictions should be swept away; but it is doubtful whether the abandonment of the nurses' home in favour of second-rate or third-rate lodgings would do anything to increase the supply of nurses. Many parents would not permit their daughters to enter a training-school, perhaps 100 miles distant from their home, if it meant their living in lodgings. The true answer to the problem is to improve the nurses' quarters and permit them to ask their friends to their rooms for tea. Who would care to entertain parents or friends in one of the common-rooms or in one of the grim little bedrooms, even were this permitted? Authorised visiting hours could be laid down.

That "living in" is not repugnant in itself, is shown by the keenness of university students to live in college rather than "digs."

There is no doubt that the corporate spirit is fostered by "living in," and this spirit is still valued by nurses.

S.R.N. 1947.

MULTIPLE-PRESSURE VACCINATION

SIR,—With the development of passenger air-transport this country is now only a few hours distant from such endemic sources of variola major as Egypt and India; and the possibility of persons incubating the disease and reaching here in an infective but undiagnosable state, or of introducing articles carrying the virus,[1] is much enhanced.

Smallpox introduced by ex-Service personnel from abroad has lately broken out in England; and this risk is likely to continue for a few more years. It follows that vaccination is no longer a relatively academic problem; and contacts, who may have already been infected when first seen, should be vaccinated by the method offering the best hope of a "take," since in these cases there is no second chance.

It is my conviction, supported by the additional evidence in Dr. Mole's recent paper,[2] that the multiple-pressure technique is less likely to fail than the standard scratch method, which is that officially advised for both civilians and the Services. During the recent war I was twice vaccinated by the scratch method, and on both occasions the absence of reaction was interpreted as being due to a high state of immunity. Before going overseas it was necessary that I should be vaccinated a third time, and having recently read an account of the multiple-pressure technique[3] I decided to try this method on myself. This vaccination was followed in about a week by pronounced local reaction (intense itching and pustulation), leading to the formation of a scab, which separated in 2–3 weeks. It is reasonable to suppose that despite the results of the two "scratch" vaccinations my previous immunity had been minimal.

I was sufficiently impressed by this result to use the multiple-pressure method when, as pathologist to a Service hospital in the Middle East, I was responsible for the vaccination state of the unit. Servicemen were vaccinated biennially in that command and on arrival at their unit overseas, no matter how recently they had been vaccinated in Great Britain.

Nevertheless, with the multiple-pressure method accelerated reactions were quite common and failures remarkably few; and not a few long-service men who had been repeatedly vaccinated with little effect were surprised at their own reactions.

More recently a colleague in this country was vaccinated by the scratch technique, with an equivocal result. Since his work brought him in close contact with variola virus it was necessary to be quite sure of his immunity. He was therefore revaccinated a few days later (using the same batch of lymph) by the multiple-pressure technique; and he developed a typical accelerated response.

In view of the mounting evidence in favour of the newer method, it would be interesting if one of the Services, in these (for them) more leisurely days of peace, were to compare on recruits the scratch and multiple-pressure techniques. With suitable organisation and a rapidly evaporating skin detergent, such as ether, the multiple-pressure technique is little, if any, slower than the standard practice. It is essential to use a sharp needle, and my preference is for a triangular cutting or Hagedorn needle, which can be touched up as required on an oil-stone. The drawing of blood, always hard to avoid on a skin rendered hyperæmic by a warm climate and the passive congestion sometimes induced by a rolled-up sleeve, seemed not to impair the result—if anything, the reverse. Excess lymph was wiped off; and, except on the rare occasions when mild secondary infection occurred from repeated trauma due to tight sleeves, a dressing was unnecessary, though it may be advisable if vaccination is carried out on a subject with dirty underlinen.

The symptom of itching was found to be a most useful guide in deciding whether a minimal reaction was due to immunity. It is easy to make a few "pressures" with the sterile needle on the cleansed skin site above the place where the lymph has been deposited; and this enables the effects due to trauma, with or without mild infection, to be distinguished from the fleeting allergic reaction often induced in the immune individual by foreign proteins in the lymph.

A minor advantage of the multiple-pressure technique is the smallness of the eventual scar, even after a primary reaction.

Liverpool.

A. C. T. VAUGHAN.

ANALGESIA IN LABOUR

SIR,—I have read the correspondence asking for wider use of gas-and-air analgesia in labour; but it is my experience, and I am sure that many other midwives will agree, that the majority of patients derive small benefit from it.

At Moreton-in-Marsh District Hospital the Oxford vaporiser with ether is used with most satisfactory results. The patient benefits without the exhausting deep inspiration necessary with Minnitt's apparatus; the mask need not be held in such close apposition to the face; it may be used for long periods without causing vomiting or affecting the force of uterine contractions; and the percentage of ether can be adjusted to suit the patient's individual need—2–3% of ether is usually sufficient during the first stage of labour, and 5–7% may be necessary towards the end of the second stage; both these percentages are well tolerated without producing cough or spasm. It is also a very great advantage that, should interference be necessary, the percentage of ether is simply increased to produce complete anæsthesia.

P. ZACHER
Sister Midwife to Moreton-in-Marsh
District Hospital.

Parliament

ON THE FLOOR OF THE HOUSE

THE House rises for Whitsun on May 23 and from the point of view of Members and of Ministers it is high time. Of late, night sittings have peppered libraries and smoke-rooms with recumbent forms, some past their first elegance, sprawling in disordered sleep. But despite difficulties the achievement of legislation is prodigious. In the last few weeks the National Service Bill, the Town and Country Planning Bill, and the National Health Service Bill (Scotland) have all been passed—not to mention the Budget debates and the Finance Bill. Indeed it is a criticism often made in Parliament at present that the Government are attempting to bring in too much legislation and to make too many changes and that they would do better to pay more attention to administration.

Exactly the same criticism can be made of world organisation, where the United Nations are attempting to bring the world back to peace, solve the question of Germany's and Japan's internal economy, while at the same time they are considering the establishment of a world police force and the world-wide economic network of their Food and Agriculture Organisation.

Viscount Bruce of Melbourne, a former prime minister of Australia and chairman of the preparatory commission on world food proposals, in a maiden speech in the Lords, pointed out that the world today had its greatest opportunity for international organisation if we went forward using the latent resources of the undeveloped countries of the world to improve the standards of the 1000 million people who were living below health level.

Neither the Labour Government in this country, nor governments in other countries, nor the world authority of the United Nations can hold back the rush of work that must be done. We must make the best arrangements we can in our national, in our Commonwealth, and in our international life to direct the forces that are urging us on. But we cannot deny their pressure, for something is happening in the world as a whole and vast changes are demanding fulfilment.

MEDICUS, M.P.

FROM THE PRESS GALLERY

University Education

We are committed to a great increase in our university population, but as Lord LINDSAY OF BIRKER pointed out in the House of Lords on May 14, we could not enlarge it without considering the effect this revolution would have upon our university system. The Government had been generous in providing money for the expansion of the universities: would they provide a little of that rarer quality—reflection—and he asked for the appointment of a departmental committee, or a subcommittee of the University Grants Committee.

University education in England was of a very high standard, but it was confined to a small proportion of the population. For instance in 1934 in Italy 1 in every 808 of the population went to a university; in Germany 1 in 604: in Sweden 1 in 543; in France 1 in 480; in Scotland 1 in 473; in America 1 in 125; but in England 1 in 1013. Yet the Barlow report had stressed that the success of our industry depends on the extent to which it is fertilised by research, and research depended on the number of scientists which the universities could supply. The Butler Act increased the need for teachers, and if we were to have a properly equipped health service we must have a far greater number of trained doctors. They ought, in his view, to be university-trained, and they ought to have some idea of what research meant. That would involve a great increase in the number of medical undergraduates.

If we were to double the number of our students—and Lord Lindsay doubted whether that would be enough—how was it to be done? Were we to ask existing institutions to preserve their character and to double their numbers? Was there room for new university colleges? These would be small but they could also be experimental, for they need not all necessarily be of the existing type. At present the universities, through shortage of staff, were finding it difficult to do their proper job. The highest training depended on the student being in close touch with the scientific swell. If you had too many students you lost your great scientist in administration. Lord Lindsay rejoiced in what the Government had done for the universities, but he thought there might be a danger of stereotyping the present set-up and making the development of university education in this country too rigid unless some body of considerable weight wrestled with these problems.

Viscount JOWITT, on behalf of the Government, agreed that our universities must have complete independence and freedom. He also agreed that our university population was much too small. The Barlow report recommended that it should be doubled in ten years, and he thought it likely that in the next ten years it would have to be doubled again. The difficulty at present was not money. The limiting factors were staff and building. The University Grants Committee estimated that the programme of development in the next five years would require £50 million, of which some £40 million was for new buildings. But the Minister of Works did not think we could undertake more than £20 million of building during the next five years.

It was not true, Lord Jowitt continued, that the University Grants Committee were in favour of developing the existing institutions, as opposed to developing new institutions. But it felt that with these shortages it was probably a better policy for the time being, if they were to achieve a rapid increase, to see how far they could get people into the existing establishments. The committee had been strengthened and had been given new and wider terms of reference. He thought therefore it would not be wise at present to appoint another committee. It would be better to stick to the University Grants Committee and give them what help they could with enlarged personnel and the apparatus of subcommittees so that they might take that all-over view which Lord Lindsay desired.

Scottish Health Bill

At the report stage of the Bill in the Lords on May 15 the following amendments were accepted:

Clause 8.—Making it clear that endowments could be allocated only for purposes within the field of the hospital services; and allowing the Endowments Commission 7 instead of 5 years in which to complete their task.

Clause 11.—Specifically requiring regional hospital boards to have wider consultations than with universities alone in framing their schemes for the constitution of boards of managements of hospitals or groups of hospitals.

Clause 14.—Providing that for dual appointments, the advisory appointments committee constituted to draw the short list of candidates should be composed half of university representatives and half of hospital representatives.

Clause 17.—Bringing within the scope of research the development of medical or surgical appliances, including hearing-aids.

Clause 34.—Conferring a right on any person to change, as well as select, their family doctor.

Clause 43.—Ensuring that doctors who were brought before the tribunal should have a clear statement of any complaints made against them at the time when they were being examined by the tribunal.

In moving the third reading Lord MORRISON thanked Noble Lords for their constructive criticisms and said the Secretary of State had been encouraged by their view that it was a better Bill for Scotland than a mere translation of the English Act would have been.

QUESTION TIME

Expenditure on Research

Mr. PHILIPS PRICE asked the Secretary to the Treasury how the estimated amount of £68,000,000 expenditure on research during the year 1947–48 is divided.—Mr. GLENVIL HALL replied: The division is as follows:

Medical Research	£698,000
Agriculture and Fisheries	£2,070,000
Industrial Research	£14,780,000
Defence Research	£49,731,000

University Grants Committee

Replying to Sir E. GRAHAM-LITTLE, Mr. H. DALTON gave the names of the University Grants Committee. The chairman is Sir Walter Moberly, the deputy chairman Mr. A. E. Trueman, F.R.S., and the medical members Prof. G. W. Pickering and Prof. J. C. Spence.

The members of the advisory committee on medical education are Sir Walter Moberly, Dr. Trueman, Professor Pickering, Professor Spence, Sir Edward Salisbury, F.R.S., Mr. L. Farrer-Brown, Mr. W. Kelsey Fry, M.R.C.S., L.D.S., Mr. G. F. Gibberd, F.R.C.O.G., Dr. H. F. Humphreys, Prof. Dorothy Russell, M.D., and Sir John Stopford, F.R.C.P., F.R.S. There is one vacancy on this committee for an expert on surgery which it is hoped to fill at an early date.

Psychiatric Cases in the Army

Replying to a question Mr. JOHN FREEMAN stated that approximately 100,000 men were discharged from the Army between September, 1939, and VJ-day on psychiatric grounds; 288,000 on account of other diseases and accidental injuries; 26,000 on account of injuries due to enemy action.

Recruitment of Nurses

Sir P. HANNON asked the Minister of Health when he would be in a position to give a definite assurance that the whole resources of the Ministry will be brought to bear on the recruitment of nurses in this country to meet the needs of hospitals and homes.—Mr. BEVAN replied: Next year, when the Act is in operation.

Production of Penicillin in Germany

Mr. S. HASTINGS asked the Secretary of State for Foreign Affairs if he would make a statement as to the present state of progress in the production of penicillin in Germany.—Mr. H. MCNEIL replied: Present production is by surface culture. Although encouraged, it does not exceed 3600 mega units a year in all four zones. The possibility of production by the deep-culture process is under discussion by the British and American authorities.

Tuberculosis in Berlin

Dr. S. JEGER asked the Minister whether he would give details of the incidence of, and the death-rate from, tuberculosis in Berlin; and what reports he had received on the outbreak of pellagra due to nutritional shortage in the U.S. zone of Germany.—Mr. BEVIN replied: The average monthly number of cases of all forms of tuberculosis reported in the first quarter of 1947 was 1696. Deaths in this period averaged 606 monthly. I have no information about any outbreak of pellagra in the United States zone of Germany.

Day Nurseries

Mr. K. LINDSAY asked the Minister whether he was satisfied that the number of day nurseries provided by local authorities was adequate to meet the needs of all the women who responded to the Government's recent appeal to enter industry.—Mr. BEVAN replied: I believe that, in general, local authorities are providing as many day nurseries, nursery schools, and nursery classes as existing resources allow. Mr. LINDSAY: Is the Minister aware that throughout the country there are springing up private nurseries for which a charge of over £1 a week is being made, and also nurseries in factories, none of which can be inspected by his department?—Mr. BEVAN: I should imagine that nurseries in factories would be inspected by the factory inspectors if they are part of the factory premises. However, I will look into the point.

Patients in Broadmoor Asylum

Mr. HECTOR HUGHES asked the Home Secretary how many prisoners there were now in Broadmoor Criminal Lunatic Asylum; how they were graded; what curative treatment was applied to them; how cures were tested and registered; how many releases had been made during the last 20 years; what were the ages of those released; and how many of them afterwards relapsed into crime or lunacy or both.—Mr. C. EDE replied: There are at present 822 patients in Broadmoor. The allocation of patients to the appropriate part of the institution, their treatment, and the degree of liberty which they can be allowed within the institution are decided in the light of the mental condition and history of each individual patient. The methods of treatment adopted are those employed in other mental hospitals, and include occupational therapy, electric convulsive treatment, and in appropriate cases psychological treatment. During the years 1927–46 inclusive, 381 patients were discharged; of these 37 (3 of whom had been charged with fresh offences) were subsequently readmitted to the asylum. Of those released during this period 7 are known to have received treatment in other mental hospitals. I regret that the other information asked for is not available.

Obituary

FREDERICK GOWLAND HOPKINS

KT., O.M., M.A. CAMB., M.B., D.SC. LOND., HON. SC.D., LL.D., F.R.C.P., F.R.S.

Sir Frederick Hopkins, who died in Cambridge on May 16 in his 86th year, was both great and greatly beloved. Living to become the Grand Old Man of biochemistry, he had long been recognised as the leading figure in the science which he did so much to develop.

His scientific renown was based on exploration of four or five avenues of biochemistry: his name will be remembered for his investigation of lactic acid in muscle activity; for the discovery of the amino-acid tryptophane, and the demonstration of its "specific biological value"; for his classical experiments on the need for accessory factors in normal diets (by which he is most widely known); and for his isolation of the cell-catalyst, glutathione (which will perhaps prove the most important of all his researches). As he once himself half-humorously said, the scientist who wishes to become famous should first discern where the next big advance is likely to come, and should then take care to be the first to start work there himself! Endowed with an instinct for scenting a trail, and with rare experimental skill in following it, he started many a scientific hunt, from which great treasures have come, and are still coming. One reason perhaps was in his mode of approach. An American pupil remarked: "The other lecturers in this university talk to you about what is already known; 'Hoppy' points out what we still don't know and still need to know." The latter approach could be the more invigorating.

But he himself would probably have been most proud to know that, in the eyes of his fellow workers, his greatest contributions were those which would not appear in *Who's Who* or the official records—that he had inspired and encouraged generations of younger men, and that he had founded the world's most distinguished, and almost its earliest, school of biochemistry.

Unusually slight in build, he had nevertheless an unmistakable dignity of carriage, and indeed a handsome presence, which at once commanded notice. Ever kindly and approachable to all, devoid of the slightest particle of "side," he won the affection and respectful admiration of his subordinates.

Born in Eastbourne in 1861, Frederick Hopkins lost his father when a small child. The confinement of school life did not appeal to one of his inquiring and roaming outlook, and for the most part he was privately educated. At the age of 17, he was placed with an insurance company in the City, but his own bent had always been scientific, and he soon determined on other courses. In turn he assisted Percy Faraday Frankland at the Royal School of Mines at South Kensington, attended lectures at University College, became an associate of the Institute of Chemistry, and then received an appointment as analytical chemist under Sir Thomas Stevenson, the Home Office analyst and medical jurist at Guy's Hospital. He was considered at one time as destined to succeed Stevenson, but wisely decided to join the medical school at Guy's and become medically qualified. His early scientific discipline as an analyst, combined with his interest in living things, provides perhaps the clue to his later achievements. For, on the technical side, his investigations consisted essentially in employing the scientific skill, resource, neatness, and precision of the expert analyst to the processes of separation, isolation, and identification, in the immensely complicated chemistry of living matter.

His scientific papers possessed a literary distinction and distinctiveness, being customarily cast in the form of a persuasive narrative, subtly phrased, and with something of the black-and-white contrasts of a Macaulay.

It is perhaps possible to trace a continuity throughout the researches which seem at first sight so varied. As a youth Hopkins had been interested in natural history, especially in lepidoptera (his first publication was a note contributed at the age of 17 to a naturalists' magazine), and his first researches were concerned with a pigment in butterflies' wings—a fascinating problem with some unexpected connexions, to which he returned in later life. The pigment proved to be a uric-acid derivative, and this led him to devise an improved technique for estimating uric acid. Interest in uric acid focused his attention on the supposed influence of dietary protein on uric-acid output—and so began the experiments with purified proteins and artificial diets.

Towards the end of the century Hopkins had been called to Cambridge by Sir Michael Foster, then professor of physiology, to develop chemical physiology (as it was then called), and he remained in Cambridge for the rest of his life. His first great discovery there was the isolation and identification with S. W. Cole in 1901 of the amino-acid tryptophane, and later with Edith G. Willcock he published one of the earliest researches on nutritionally essential amino-acids, showing that zein, an incomplete protein of maize, could be improved nutritionally by the addition to it of tryptophane.

Press Portrait Bureau

Animal feeding studies of this kind with purified diets soon convinced Hopkins, as it had convinced others before, that normal growth could not be sustained on the known "major constituents" of diets, and that still unidentified "accessory food factors" were needed in addition. But he went one step further than any of his predecessors in suggesting that these accessory factors present in *normal diets* were one and the same as the substances needed to prevent *deficiency diseases*. As he put it in a lecture to the Society of Public Analysts in 1906: "In diseases such as rickets, and particularly in scurvy, we have had for long years knowledge of a dietetic factor; but though we know how to benefit these conditions empirically, the real errors in the diet are to this day quite obscure. They are, however, certainly of the kind which comprises these minimal qualitative factors that I am considering."

It was appropriate, therefore, that a good many years afterwards, when the new view had become firmly established, Hopkins was to share a Nobel prize in medicine with Eijkman who had been the first in 1890 to produce a deficiency disease (beriberi) experimentally and to recognise (along with Grijns 1901) that it was due to the lack of something from the diet.

Hopkins's famous paper in the *Journal of Physiology* in 1912 (Feeding Experiments Illustrating the Importance of Accessory Factors in Normal Dietaries) did more than anything to convince his contemporaries of the truth of the then still heretical doctrine that man cannot live by fat, protein, and carbohydrate alone, but that organic accessories are necessary. After this, progress was rapid, although Hopkins himself published relatively little more on the subject: the "vitamine hypothesis," as it was at first, grew into a reality . . . and the number of vitamins still grows.

In the meantime, Hopkins's association in Cambridge with a leading expert on muscle physiology, Walter Fletcher (later the first secretary of the Medical Research Council), led to their collaboration in the celebrated study which helped to clarify the phenomenon of the production of lactic acid in muscular activity.

Returning to his interest in accessory factors, Hopkins gave his attention to the sulphur-containing substances in food, and eventually traced the sulphydryl reaction back to its source. By 1921 he could announce the isolation of the "autoxidisable constituent" of the cell, which he named glutathione. In 1929 he established its precise constitution as a tripeptide. From glutathione followed other important studies relating to tissue oxidation.

In all, he published around 100 papers, including scientific communications and presidential and inaugural addresses. One of his last public appearances was at the inaugural meeting of the Nutrition Society in Cambridge in 1941, when he gave an inspiring introductory address, in which he looked back over the past half-century's work and concluded by blessing the new venture.

Despite declining health and a growing loss of sight in his last years, he retained his intellectual vigour and all his kindness and charm and magnetism.

L. J. H.

His life, from its strenuous beginning up to those declining years in silence and darkness, was one of almost continuous, and happily fruitful, labour. His long familiarity with actual work at the bench, added to his natural genius and untiring application, endowed him with an uncanny flair for a theme and for brilliant methods of attack.

A chemist by instinct, he was one of those earliest pioneers who had faith in the importance of chemistry to the medical sciences, and in particular to the subject of physiology: he was chiefly instrumental in the establishment of biochemistry as an independent subject in England.

His publications, for so famous a man, were not numerous, but they were, almost without exception, of superb value and distinction. Nearly all were individual, the product of his own hand and mind, and nearly all were spearheads of advance into new territory, still yielding harvests to many workers who followed after. He had no pupils and founded no school, in the modern sense of groups of led, or driven, teams. He was a man of simple ways.

C. L. E.

There is extant a large almost full-length portrait of Michael Foster, picturing him in front of a blackboard which carries chalked on it, in characteristic bold Fosterian handwriting, the sole word "proteids." "That dates it," said someone looking at it: "Pre-hopkins." So prevailing was Hopkins's *maitrise* in his subject that his own fame and that of his subject are identical over large tracts of inquiry.

Already by 1899 his position as a biochemist was pre-eminent. The University of Liverpool at that time founded what was, I fancy, the first chair in biochemistry to be endowed in this country, and offered it to Hopkins. But Cambridge had, through the prevision of Michael Foster, already secured him. He went forward from discovery to discovery. His ways were his own. There was curiously little reflex of Continental work; such liaison as there was seemed to trace mainly across the Atlantic.

I have memory of an address given by him at a British Association meeting. In an uninviting gaunt lecture-room he decanted for nearly an hour on the cell as a theatre of chemical processes. Without any deliberate attempt at eloquence, and in a voice that as he became more interested fell to such a purely conversational level as to be a little difficult to hear, he conjured up for his audience—some 30 persons all told—a picture of the cell as a tiny sponge-work containing perhaps a thousand foci of different actions coöperatively confined within a unitary whole. An organised factory manifoldly hydrolysing, pulling to pieces, and contemporaneously constructing and reconstructing. And this unity bounded outwardly by a mosaic of countless chemical poles and leaking like a sieve. As I listened I felt I was being privileged for the time to see something of the microcosmic world in which my friend's scientific thoughts took shape and did his bidding. One mental factor which, it seemed to me, such thinking must demand, was a peculiar intensity of visual imagination, continuously checked in factual knowledge. The great organic chemist, conjuring with stereographic formulæ, must have something of the same faculty. It is lived with. Kekule hit on his famous key-formula when riding on a London bus.

Hopkins owed little to Continental influence. He was a Londoner; his speech mildly declared it. On his 80th birthday he gave a talk in a small room—he was best in a small room—in his laboratory to pupils working then with him. The subject was his own career and what he inferred from it. I fancy that after biochemistry his greatest interest lay in "Socialism." His views were quite far to the "Left." He had associated with Ramsay MacDonald in the early days of both of them. He remained a propagandist. However, he was a biochemical discoverer first and foremost. Even in the last years when health was failing he paid a visit to the laboratory almost daily to pursue original inquiry at first hand.

C. S.

Sir Frederick Hopkins's monumental discoveries in biochemistry are well known. But it is not alone in their published works that great scientists influence advance in their chosen fields; in addition, as teachers, they are indirectly responsible for progress and achievement in fields sometimes closely allied but often far removed from their own.

Most men of Hopkins's calibre set out to train successive generations of junior workers who go forth to practise the master's methods and spread his views. It is doubtful whether, in this sense, Hopkins ever trained anyone; his intuitive habits of thought and his uncanny and incommunicable skill in handling material largely precluded this method of teaching. Nevertheless his scientific influence on workers of many nationalities and at all stages of development was stupendous. On entering his department one was immediately in close touch with the professor; the contact was maintained in an apparently haphazard manner but was close, intimate, and fructifying. The newcomer quickly gained the impression that he himself was a person of scientific importance and that his work and thoughts were of great interest to the professor; also that he too was a person capable of original thought.

The gift of producing this impression was most apparent at the weekly tea-club meetings. Here each worker in turn was invited to give an account of some piece of research in progress or just finished. Though such communications varied in value and might even occasionally appear dull or unimportant, as soon as the professor opened the discussion the subject was illuminated, the facts were placed in perspective, and interesting implications were pointed out. By the time the chairman had finished his remarks everyone, including the author, was convinced of the value and significance of the communication.

The professor's weekly lectures were regarded as occasions never to be missed. They were frequently reminiscent in character and historical in form; they were attended as a matter of course by every member of the department in the hope, never disappointed, of hearing old facts and theories take some new and significant shape as they passed through the professor's mind.

Hopkins was so available to all and sundry that it was a matter of surprise that he found time for his research. Yet research was his great preoccupation and indeed his only hobby, and Sunday mornings always found him in his laboratory, when, so he said, he carried out experiments too foolish for his assistant to know about. When at work he employed an intense concentration. His gift, which he never seemed able to impart, of separating crystalline compounds of great physiological importance from complex messes, was found, when one was privileged to see it in operation, to be due to an intensely acute observation and a retentive memory for important detail.

One of his poses was an ignorance of organic chemistry, but no organic chemist who ever conversed with him on the types of compounds he had studied was able to substantiate this claim.

He has gone, but his influence remains, not only in his published works and in the records of the Royal Society but in the many minds he stimulated and enriched.

D. M. N.
M. S.

I have good reason to remember the consideration and generous encouragement he gave to his pupils and junior colleagues. In Vienna after the first world war the small team commissioned by the Medical Research Council and Lister Institute to investigate the ætiology of rickets received a kindly visit from him. Not only did his prestige enhance the value of the unit in the estimation of its Austrian colleagues, but the sympathy he showed for the workers, and his appreciation of the difficulties inherent in the research itself as well as in its prosecution under the existing conditions, remained a lasting encouragement and an inspiration for the continuance of the work.

H. C.

In the years round about 1910 Hopkins, whom we then regarded especially as the discoverer o tryptophane, gave at Guy's Hospital medical schoo occasional advanced lectures in physiology for th University of London. The lectures were wonderfu in their matter, but not attractive to students in delivery At that time he was engaged in a systematic search fo "the accessory food factor," the absence of which in a synthetic diet led to cessation of growth. After one o these lectures, during tea in the physiological laboratory, he told us, in a rather despondent tone, that "it isn't creatine"—meaning of course that he had devoted an experiment to the addition of creatine to the synthetic diet with a negative result. Nowadays when it is difficult to keep abreast of the literature relating to even a single one of the many "accessory factors," the statement that "it isn't creatine" may seem rather meagre; at the time it was a comprehensive report on the present *state of vitamin research by our greatest biochemist.* He had at that time one-half of his life still before him, and the vast increase in knowledge which has taken place in that time demonstrates what can be done under modern conditions when the beginning of the right path is found by pioneers like Hopkins.

E. L. K.

I first met Gowland Hopkins at Guy's Hospital in 1883. At that time he was assistant to Thomas Stevenson, and it was his duty to prepare the experiments for Stevenson's chemical lectures, in addition to analytical work in connexion with famous poisoning cases. He was a highly skilled chemist; I was a first-year student commencing the study of the medical sciences.

Finding I was interested in chemistry, he kindly allowed me to potter about in his laboratory at odd times, and when he was not too preoccupied he would discuss chemical problems in physiology which interested and perplexed me. I remember the consideration he gave to my crude imaginings and the delicacy with which he demolished them. The benefit of these unceremonious talks was gratefully appreciated and I became perhaps the first of his loving pupils.

As we became intimate in those old days at Guy's, I had the youthful effrontery to urge him to abandon his career as an analyst, study medicine, and subsequently devote his chemical talents to researches in physiological chemistry. At first he was amused, and then attracted to the idea; but, although he was enterprising enough to contemplate a further four years of studentship with equanimity, for financial reasons the proposition was an impracticable one. However, a few years later he did embark on the medical course, and he qualified in 1894. After a while as demonstrator with Starling at Guy's, he accepted an invitation from Michael Foster to join the staff of the department of physiology at Cambridge. To my mind, his pre-eminence as a biochemist was due to the perfect fusion of his knowledge of chemistry and physiology, in the disciplines of both of which he was equally at home.

Hopkins was the gentlest, kindest, and most modest man I have known. He was not uncritical, but I cannot recall hearing him say an unkind word about anyone. The universality of his kindness was almost a defect, for sometimes a little ruthlessness appeared to be more appropriate to the situation. His modesty was such that when one discussed a subject of which one was ignorant and he was a master, he somehow managed to suggest that it was he who had benefited by the conversation!

A great man and a good friend has gone from among us. His departure is mourned by young and old, but the memory of "*Hoppy*" will long remain an inspiration to those who have enjoyed the privilege of working with him.

C. J. M.

While at Guy's Hospital, in 1896, Hopkins took part in establishing the Clinical Research Association, offering a pathological service to practitioners, and gave it much hard evening work. In his early days at Cambridge he was supervisor of medical studies at Emmanuel College, but in

910 his election into an honorary “ prelectorship ” in physioogical chemistry at Trinity College enabled him to devote his time more fully to biochemical investigation and teaching. n 1902 a university readership in chemical physiology had been reated for him ; in 1914 he was given a special professorship n biochemistry ; and in 1921 he became the first holder of the Sir William Dunn chair of biochemistry and head of the associated Sir William Dunn institute.

He was an original member of the Medical Research Council and the first chairman of its Accessory Food Factors Committee. He was elected a fellow of the Royal Society in 1905, and became its president in 1931. He was knighted in 1925, was chairman of the British Association in 1933, and vice-president of the Chemical Society in 1921. Among his numerous honours and distinctions may be counted the Royal medal and the Copley medal of the Royal Society, the Baly medal of the Royal College of Physicians, the Society of Apothecaries' medal, and the Albert medal of the Royal Society of Arts. He received the Nobel prize for medicine in 1929, and was appointed to the Order of Merit in 1935. In 1938 he was awarded the Conway Evans prize by the presidents of the Royal Society and the Royal College of Physicians.

He is survived by his life's comrade and helpmate, Lady Hopkins, who before their marriage in 1898 was Jessie A. Stevens. Their son, Frederick Hopkins, is a doctor, and their two daughters, Barbara Holmes and Jacquetta Hawkes, are well known for their research and publications in biochemistry and archæology respectively.

ALAN GORDON ADRAIN

M.R.C.S.

Dr. Alan Gordon Adrain, who died on April 28 in Durban, worked for a time on the Congo as a pharmacist before he came to this country to study medicine at St. Mary's Hospital. In 1928 he took the Conjoint qualification, and after holding a resident appointment at the Royal Northern Hospital he returned to South Africa, where he took up practice in Zululand. At the time of his death he was senior medical officer to a large group of sugar plantations in Natal.

As medical officer to the Durban division of the old South African R.N.V.R., Adrain was mobilised on the outbreak of war in 1939. He saw extensive service afloat, and later was appointed liaison officer at Durban, where his cheery presence and comprehensive local knowledge eased the problems of visiting naval medical officers. A man's man, Adrain was a fine example of the resourceful single-handed practitioner. A visit to Stanger meant the traditional hospitality of South Africa and a round of the hospital and outlying clinics with the accompanying shop so missed at sea.

Dr. Adrain married Miss Norah Collins, S.R.N., and they had two children.

W. S. P.

Public Health

Smallpox

Two further cases of smallpox have been reported in connexion with the outbreak at Bilston. One was in an unvaccinated woman, aged 27 years, who was taken ill on May 9 and developed a scarlatiniform rash on May 12. On the 16th it was recognised that she was suffering from hæmorrhagic smallpox and she was removed to hospital, where she died the same day. The source of her infection is at present unknown. At Birmingham a medical student who visited the Bilston Smallpox Hospital on April 24 and was unsuccessfully revaccinated the same day has developed a mild attack of smallpox with an atypical eruption.

A patient with smallpox was removed to hospital from a Salvation Army hostel in Bermondsey on May 16. This was an unvaccinated man, aged 22 years, who had come to London from a lodging-house at Barnsley on May 6. His illness began on May 12 and the rash appeared on the 16th. Inquiries at Barnsley revealed that three residents of the lodging-house where the Bermondsey patient had stayed were suffering from smallpox. In two men, aged 72 and 76 years, the onset appears to have been on May 12 and in a woman, aged 50 years, on the 15th. All were removed to a smallpox hospital on May 16.

Infectious Disease in England and Wales

WEEK ENDED MAY 10

Notifications.—Smallpox, 2 ; scarlet fever, 1002 ; whooping-cough, 2222 ; diptheria, 194 ; paratyphoid, 3 ; typhoid, 6 ; measles (excluding rubella), 10,134 ; pneumonia (primary or influenzal), 561 ; cerebrospinal fever, 74 ; poliomyelitis, 12 ; polioencephalitis, 2 ; encephalitis lethargica, 0 ; dysentery, 110 ; puerperal pyrexia, 151 ; ophthalmia neonatorum, 73. No case of cholera, plague, or typhus was notified during the week.

One case of scarlet fever was notified at Coseley, Staffs, the other at Sheffield. Of the 110 cases of dysentery, 72 were notified in Lancashire *(including 40 at Prestwich, 18 at Liverpool, and 10* at St. Helens).

Deaths.—In 126 great towns there were no deaths from scarlet fever, 1 (0) from an enteric fever, 1 (1) from diphtheria, 5 (0) from measles, 15 (2) from whooping-cough, 95 (14) from diarrhœa and enteritis under two years, and 10 (0) from influenza. The figures in parentheses are those for London itself.

The number of stillbirths notified during the week was 263 (corresponding to a rate of 25 per thousand total births), including 31 in London.

Catching Up

Since the end of the war the following reports have been published by the Registrar-General :

Statistical Review for 1941, tables, part I—March, 1946.
„ „ „ 1941, tables, part II—July, 1946.
„ „ „ 1942, tables, part I—October, 1946.
„ „ „ 1942, tables, part II—May, 1947.
„ „ „ 1938 and 1939, text volume—May, 1947.
Decennial Supplement for 1931, part IV, Multiple or Secondary Causes of Death—April, 1947.

The Statistical Review for 1945, tables, parts I and II, will be published within the next two or three months, and it is hoped that the corresponding volumes for 1943 will appear before the end of this year.

Diary of the Week

MAY 25 TO 31

Tuesday, 27th

ROYAL COLLEGE OF SURGEONS, Lincoln's Inn Fields, W.C.2
5 P.M. Mr. William Gissane : Tendon Injuries of the Hand.
ROYAL SOCIETY OF MEDICINE, 1, Wimpole Street, W.1
8 P.M. *Medicine.* Dr. E. R. A. Merewether, Dr. Charles Fletcher, Prof. Matthew Stewart : Pneumonoconioses.
LONDON SCHOOL OF DERMATOLOGY, 5, Lisle Street, W.C.2
5 P.M. Dr. Hugh Gordon : Cutaneous Affections due to Sunlight.
EDINBURGH POSTGRADUATE BOARD FOR MEDICINE
5 P.M. (Royal Infirmary.) Dr. Reginald Passmore : The Fat of the Land.

Wednesday, 28th

ROYAL COLLEGE OF SURGEONS
5 P.M. Sir Reginald Watson-Jones : Fractures of the Neck of the Femur.
ASSOCIATION OF INDUSTRIAL MEDICAL OFFICERS
2.45 P.M. *Scottish Group.* (Institute of Hygiene, University of Glasgow.) Dr. D. M. Watson : Industrial Sickness Absence. Dr. Edward Collier : Prevention and Control of Industrial Oil Dermatitis.

Thursday, 29th

ROYAL COLLEGE OF SURGEONS
3.45 P.M. Dr. L. W. Proger : pathological specimens (Erasmus Wilson demonstration).
5 P.M. Mr. S. A. S. Malkin : Conservative Treatment of Bone and Joint Tuberculosis.
6.15 P.M. Mr. B. H. Burns : Open Fixation in Fractures of the Shafts of Long Bones.
LONDON SCHOOL OF DERMATOLOGY
5 P.M. Dr. J. L. Franklin : Cutaneous Syphilis.
UNIVERSITY OF DURHAM
5.15 P.M. (Royal Victoria Infirmary, Newcastle-on-Tyne.) Prof. G. Grey Turner : Rutherford Morison and his Achievement in Surgery (Rutherford Morison lecture).
EDINBURGH POSTGRADUATE BOARD FOR MEDICINE
4.30 P.M. (Royal Infirmary.) Prof. R. J. Kellar : Endometriosis (Honyman Gillespie lecture).

Friday, 30th

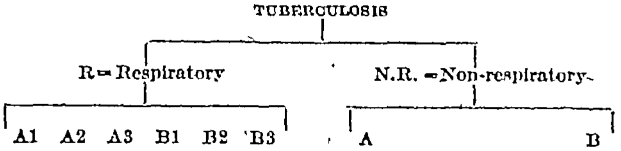
ROYAL COLLEGE OF SURGEONS
5 P.M. Miss Maud Forrester-Brown : Operative Procedure in Poliomyelitis
6.15 P.M. Mr. W. Rowley Bristow : Derangements of the Knee-joint.
MEDICO-CHIRURGICAL SOCIETY OF ANDERSON'S COLLEGE AND ST. MUNGO'S COLLEGE
7.30 P.M. (Royal Infirmary, Glasgow.) Sir Stanford Cade : Recent Advances in the Treatment of Cancer.

Notes and News

TUBERCULOSIS CLASSIFICATION

THE Minister of Health has adopted recommendations by the Joint Tuberculosis Council for the revision of the classification and terms to be used in annual returns. Under the new classification, published as an amended version of part of the appendix to memorandum 37/T (revised), tuberculous patients will be divided into classes A and B, according to whether tubercle bacilli have not or have been recovered. Patients may be transferred at any time from class A to class B; but those from whom tubercle bacilli have not been recovered within the first eight weeks of observation should be placed in class A. Single positive bacteriological reports, unconfirmed by further search and unsupported by clinical or radiological evidence of tuberculosis, may be ignored.

Respiratory cases are to be further divided into three groups: (1) group 1, in which constitutional disturbance is slight, and there are few signs or radiological changes; (2) group 3, in which there is profound systemic disturbance or constitutional deterioration, and pronounced impairment of function; and (3) group 2, to include all cases which cannot be placed in groups 1 and 3. We thus have the following scheme:



An uncomplicated pleural effusion for which no other cause can be found should be regarded as tuberculous, and the case placed in group 1 of class A or B, according to the bacteriological report on the fluid.

PROTECTION AGAINST RADIOACTIVE SUBSTANCES

NEW rules for the protection of those working with radioactive substances have been announced by the Minister of Labour. In the Factories (Luminising) Special Regulations, 1947, it is laid down that all employees working with or near luminous compound shall be examined within seven days of starting work, and thereafter at intervals of not more than one month; and a health register, to include all employees, must be kept. Those engaged in the manipulation of luminous compound are to wear photographic film for one week in every three months. This is to check the sufficiency of other precautions, which include the prohibition of more than 48 hours' work a week, and provision for three months in other employment after each full year's employment on processing. Measures are also given for keeping the air and all surfaces free from luminous compound and for direct protection by special clothing and by screening.

INJECTIONS WITHOUT NEEDLES

A Detroit engineer has invented an instrument for injecting solutions directly through the skin. A British United Press report describes the apparatus as a metal cylinder about the size of a flashlight, with a powerful spring inside. The ampoule containing the solution is fitted into the end of the cylinder and this is placed on the patient's arm. The doctor then presses the button and the solution, forced through a hole 1/300 inch in diameter at a pressure of 3200 lb. per sq. inch, passes through the skin in a fraction of a second, causing no pain. The idea of the apparatus came from the observation that oil from diesel engine jets often penetrates the skin of engineers.

RURAL WATER

THE uneven development of our water-supplies was deplored by Mr. Aneurin Bevan, Minister of Health, in his speech at the centenary conference of the British Waterworks Association on April 23. It was a reproach to us, he declared, that so much of rural England still lacks piped water. But the Rural Water Supplies and Sewerage Act of 1944 provided £15 million towards the cost of water schemes and projects to the value of over £20 million had been submitted of which £4 million-worth had been approved. These schemes had to be considered critically, for often those which satisfied local requirements proved to be inadequate against a background of wider needs. The surveys of these larger areas which were now being undertaken by technical officers of the Ministry and the county councils would prove invaluable in designing a national water-supply on a regional basis. The rural water-supply must keep pace with the hoped-for expansion of rural housing; for, said Mr. Bevan, "we must not make th agricultural worker's wife a beast of burden or she will be dissatisfied, and she won't be long in conveying dissatisfaction to her husband and then we shall lose agricultural workers."

A MORE SENSITIVE WASSERMANN REACTION

No serological reactions have been more intensively stud than the complement-fixation and precipitation tests for t diagnosis of syphilis, and they must hold the record for t number of modifications and refinements of technique devis to increase their sensitivity According to a British Unit Press report from Washington, workers at Duke Universit under the auspices of the U.S. Public Health Service, ha isolated and concentrated a serum protein fraction which th have identified as the reagin responsible for the positi Wassermann reaction, and they have isolated another fracti which has a specifically inhibitory effect on the "reagi concentrate" in a false-positive but not on the "reagi concentrate" from sera of known syphilitics. On this bas a practical test has been devised, and the results from more th 2500 sera indicate that "practically all sera from patien with clinically diagnosed syphilis give the syphilitic type reaction." More detailed reports will no doubt appear shortl

EXECUTIVE COUNCILS

THE statutory rules and regulations (no. 889) have no been published dealing with the executive councils whic under the fifth schedule of the National Health Service Ac are to be set up to deal with general medical services of eac local health area. Most local authorities and local medic committees have already sent the names of those they hav appointed to the Minister who is now considering the appointments he will make. The term of office of members of th councils as laid down by the new rules will be three years, an a third of the council will retire annually.

MEDICAL BENEFITS FROM MILITARY SERVICE

IN a survey of the medical advantages gained by thos accepted for universal training in the United States Army Major-General Norman T. Kirk, the surgeon-general, enumerated: (1) the thorough application of preventive medicine giving maximum protection against smallpox, enteric fever tetanus, influenza, and other communicable diseases; (2) th periodic physical examinations, which often uncover unsuspected pathological conditions; (3) the high standard o medical and hospital care; and (4) the rigid sanitation In the army, he said, there is no deterrent, as there sometime is in civilian life, to seeking prompt medical attention; an the greater ease of gaining admission to hospital often mean a shorter illness and fewer complications. "The situation i the army," said General Kirk, "is unique in the action whic can be taken in the various fields of safeguarding health There is no other comparable situation where entire group of men can receive thorough training and indoctrination i the principles of health protection." Under a system of universal training, the army by medical care and education would offer benefits which would accrue "not only to these young men themselves but also inevitably to a certain degree to their families, communities, and to the entire country."

FOOD AND HOW TO EAT IT

A NEW journal on nutrition—*Nutrition, Dietetics, Catering*—is to give quarterly official news of the British Dietetic Association and the Food Education Society. In a foreword to the first issue, Sir Jack Drummond, F.R.S., remarks that we have a grand tradition of good cooking in this country, dating from the prosperous early years of the 18th century, but that it has since been beaten down by many depressions, during which the well-to-do took to bastard French meals and the poor, in their poverty and ignorance, "boiled the life and soul out of their daily dinners." The journal takes up arms against bad cooking and bad catering in this country. We hope, with Sir Jack, that those who guide its policy "will prudently and happily marry scientific instruction to gastronomic appreciation." The first issue certainly offers a fine international menu for the discriminating palate: Prof. J. R. Marrack on food or nutrients, Prof. John Yudkin on nutrition in West Africa, Miss Diana J. Ten Haaf on the food-supply of the Netherlands during the war, Mrs. D. Elrene Palmstrom on food habits in Norway, and Miss J. Isobel Mills on the diploma course in dietetics at Leeds. The text makes rather hungry reading, but, provided good digestion waits on appetite, readers will find themselves mentally nourished. We congratulate the anonymous editor on his fare.

iversity of Cambridge

On May 10 the following degrees were conferred :

M.D.—J. A. Dudgeon, C. R. Morison, J. M. Naish, E. A. Pask.
M.B., B.Chir.—J. G. Kilner (by proxy).

niversity of Sheffield

Dr. J. G. McCrie has been appointed full-time dean of the ulty of medicine.

Dr. McCrie, who will take up his duties on Sept. 1, has been ior administative officer in the school of medicine of the Univer- y of Leeds. A native of Edinburgh, he graduated at the university medicine with first-class honours in 1925, and after holding ident hospital posts he became clinical tutor and senior clinical istant at the Edinburgh Royal Infirmary and assistant in the partment of medicine of the university. Later he was appointed turer in medicine in the University of Edinburgh, assistant ysician to the Royal Infirmary, and physician and deputy ector of the medical unit in the Edinburgh municipal hospitals. ring the late war he served as a physician in the Army in France d later in North Africa and Italy, rising to the rank of colonel d being awarded the O.B.E.

Dr. G. L. Hermitte has also been appointed lecturer in stology, and Dr. F. T. Thorpe lecturer in mental diseases.

niversity of Manchester

The following appointments have been made: Dr. H. J. rennan, lecturer and director of the subdepartment of æsthetics; Dr. F. A. Langley, *lecturer in gynæcological* athology; Miss Annie Hain, D.SC., lecturer in gynæcological ndocrinology; Dr. Harold Jackson, lecturer in bacteriology; r. F. B. Jackson, assistant lecturer in bacteriology; Dr. . G. Reid and Dr. W. McL. E. Topping, assistant lecturers radiology: Dr. G. W. Boden, assistant lecturer in radio- erapy.

oyal College of Surgeons of England

The War Organisation of the British Red Cross Society and rder of St. John of Jerusalem have made a grant of £20,000 o the college towards the cost of replacing its museum which as partly destroyed by enemy action. They have made the ift in recognition of the help the Red Cross and St. John have eceived from the medical profession.

Jacksonian Prize.—The subject for this prize for 1947 is he Surgery of the Lower Œsophagus and Cardiac End of he Stomach, and dissertations must reach the college by P.M. on Dec. 31. The subject for 1948 is Malignant Disease f the Thyroid Gland. Further information may be had from he assistant secretary of the college, Lincoln's Inn Fields, ondon, W.C.2.

The first number of the *Annals of the Royal College of urgeons of England* will be published in July. The journal, hich is to appear monthly, will contain college lectures, ews, and a diary of forthcoming events. The annual sub- cription is 25*s*. post free, and the cost of single numbers will e 2*s*. 6*d*. plus postage.

oyal College of Physicians of Edinburgh

At a meeting of the college held on May 6, with Dr. D. urray Lyon, the president, in the chair, the following elections ere made :

Fellows.—P. M. Wood (Halifax, Yorks), R. A. Bennett (London), . E. Elliot (Edinburgh), C. L. Grant (Chislehurst, Kent), J. D. llan (Bothwell), G. M. Greig (Watford, Herts), T. F. Rodger Glasgow), Harold Scarborough (Edinburgh), R. W. Craig (Edinburgh).

Members.—H. E. Seiler, Jacobus Siebert, S. L. Forrest, N. A. ossiter, D. A. Duthie, W. A. L. MacFadyen, H. A. Reid, D. C. oss, C. H. Davidson, C. G. Robertson, J. M. Staveley, A. G. S. Hill, . R. C. Batchelor, A. J. A. F. Al Amari, H. N. Robson, B. B. ukherji.

oyal College of Surgeons of Edinburgh

At a meeting of the college on May 15, with Mr. James M. raham, the president, in the chair, the following were dmitted to the fellowship :

Abdel Hamid Ahmed El Baghdadi, M.R.C.S., W. E. B. Boscence, .B. Adelaide, G. P. Charlewood, M.B. Cape Town, G. R. Clarke, .B. Birm., Norah H. C. Clarke, M.B. Lond., A. D. Cuthbert, M.B. lasg., George Degnan, M.D. McGill, A. C. Duncan, M.D. Manitoba, . G. A. Du Toit, M.B. Cape Town, Ahmed Talaat El-Mansuri, .B. Cairo, H. C. Fishman, M.D. Manitoba, T. G. Fyshe, M.D. McGill, F. G. Hollands, M.R.C.S., M. J. Lange, M.R.C.S., J. E. Leddy, M.D. McGill, J. T. MacDougall, M.D. McGill, A. B. McLean, M.B. Melb., E. B. Z. Masterman, M.R.C.S., Bindra Ban Ohri, M.B. Punjab, Donald Robertson, M.B. Edin., J. C. B. Sergeant, M.B. Edin., Tulsidas Prabhudas Shah, M.B. Bombay, L. G. P. Shiers, M.R.C.S., Samuel Skapinker, M.B. Witw'srand, Cyril South, M.B. Sheff., R. Y. Stevenson, M.B. Lond., A. M. Stewart, M.B. Edin., Dattatraya Vishnu Virkar, M.B. Bombay, Sydney Wassyng, M.B. Witw'srand, B. W. Wells, M.R.C.S., T. E. Wilson, M.D. Melb., Benjamin Winter, M.D. Toronto, James Wishart, M.B. Glasg., G. N. Wright, M.B. Lond., R. B. Wright, M.B. Glasg.

Society of Physiotherapists

This society, which was founded 15 years ago as the Association of Bio-Physical Assistants, has now been wound up. The Chartered Society of Physiotherapy has agreed to accept biophysical assistants, on the society's sponsorship, for enrolment on the C.S.P. register.

C.B.C. Mothers' Clinic

On Thursday, June 5, at 2.30 P.M., Mrs. Marie Stopes, D.SC., will give a demonstration on contraceptive technique. Tickets are only obtainable in advance from the clinic, 108, Whitfield Street, London, W.1.

Rheumatic Fever Library

The University of Colorado School of Medicine is collecting reprints of all articles dealing with rheumatic fevers. When the material is assembled it will be cross-indexed and made available to workers of all countries through a 'Photostat' and abstract service. The address of the library is 4200, East Ninth Avenue, Denver, 7, Colorado.

Admission Officer

The London Hospital is creating a new medical appointment of senior admission officer with a salary of £750 per annum non-resident (or £650 resident). The holder will rank above the first assistants and registrars, and will be responsible for the admission and distribution of all patients, and for the clinical work of the receiving-room, where he will be required to teach medical students. Further particulars will be found in our advertisement columns of May 17.

Association of Surgeons of Great Britain and Ireland

The annual meeting of the association will be held in Oxford on July 3, 4, and 5 under the presidency of Sir Hugh Cairns. Mr. J. H. Kellgren, Dr. W. K. Livingston, Prof. J. Paterson Ross, and Prof. Geoffrey Jefferson, F.R.S., will open a discussion on the Surgical Relief of Pain; Mr. Geoffrey Keynes, Prof. H. P. Himsworth, Mr. T. A. Hindmarsh, and Dr. Oliver Cope on the Modern Treatment of Toxic Goitre; and Mr. P. R. Allison, Dr. L. G. Blair, Mr. T. Holmes Sellors, Mr. Vernon Thompson, and Mr. N. C. Tanner on Cancer of the Cardiac End of the Stomach and Lower End of the Œsophagus. Further information may be had from the offices of the association, 45, Lincoln's Inn Fields, London, W.C.2.

Commonwealth Fund

Dr. Donal Sheehan, professor of anatomy of the New York University College of Medicine, has been appointed general director of the Commonwealth Fund in succession to Mr. Barry C. Smith.

Dr. Sheehan, who is 40 years of age, graduated B.SC. at the University of Manchester in 1926 and M.B. three years later. In 1932 he was awarded the gold medal for his M.D. thesis, and in 1936 he obtained his D.SC. for research into the anatomy of the autonomic nervous system. He held the lectureship in neurological anatomy in the University of Manchester for two years before he was appointed to his American chair in 1937. During the war he acted as dean of the College of Medicine. He is a trustee of the Josiah Macy, Jr., Foundation and recently completed a mission in Czechoslovakia for the Rockefeller Foundation.

Colonial Studentships

On the recommendation of the Colonial Medical Research Committee, ten studentships are being offered to British graduates in medicine and cognate sciences who wish to prepare themselves for research in tropical medicine. The studentships will carry an allowance of £260 per annum, free of income-tax, and will normally be held for two years. They will be tenable at any university or other appropriate institution. It is intended that students who successfully complete their courses will be offered posts in the projected Colonial Medical Research Service. Application should be made, through the head of the candidate's department, to the secretary, Colonial Medical Research Committee, Colonial Office, London, S.W.1.

The National Association for the Prevention of Tuberculosis is also offering six scholarships to doctors and other medical personnel of the British Colonial Empire who wish to study tuberculosis in Britain for six months. Two scholarships (value £120 each) will be open to doctors in the Colonial Medical Service; two (value £100 each) to medical graduates of native medical schools in the British Colonies; and two (value £80 each) to matrons, nurses, health visitors, or other members of Colonial sanitary departments. Applications should be made through the Colonial medical departments, who will forward them to the Colonial Office, which will make recommendations to the council of the N.A.P.T.

A Psychologist on Germany

Dr. H. V. Dicks, professor of psychiatry in the University of Leeds, will broadcast on German Character Structure in the Third Programme at 6 P.M. on Whit Monday.

Short-wave Congress

An international short-wave congress will be held in Amsterdam from July 19 to 24, 1948. Further information may be had from the secretary's office, Weteringschans 73, Amsterdam.

Anæsthetic Appointments

Dr. E. A. Pask has lately taken up his appointment as director of anæsthetics at the University of Durham. Dr. W. W. Mushin has been appointed to the post of director of the department of anæsthetics in the University of Wales, and he will begin work at Cardiff in July. Both have been assistants in the Nuffield department of anæsthetics at Oxford.

British Association of Urological Surgeons

The annual meeting of the association will be held in Glasgow on June 13 and 14 at the hall of the Royal Faculty of Physicians and Surgeons, 242, Vincent Street. There will be a discussion on tumours of the bladder, and short papers will be read by Mr. Hugh Donovan, Mr. W. M. Borthwick, Mr. W. S. Mack, Dr. H. H. Pinkerton, and Mr. Hamilton Bailey. Films will also be shown by Mr. T. J. Millin, Mr. David Band, Mr. T. L. Chapman, and Mr. E. W. Riches, and there will be operating sessions at the Western Infirmary, the Royal Infirmary, the Victoria Infirmary, and the Royal Cancer Hospital.

Lebanon Hospital for Mental Diseases

Dr. R. B. Robertson has been appointed medical superintendent of the Lebanon Hospital at Asfuriyeh at Beirut

Dr. Robertson, who is 33 years of age, graduated M.B. at the University of St. Andrews in 1935, and in the following year went to Ethiopia, where he worked throughout the Italo-Abyssinian war as second-in-command and surgical specialist of the British Red Cross ambulance unit. Later he joined the R.A.M.C. and served in India and Palestine. At the outbreak of war he became second-in-command of a field ambulance in the Western Desert, and was mentioned in despatches. After two years as D.A.D.M.S. at Cairo headquarters, in 1943 he was appointed O.C. a field dressing-station which he took to Tripoli and Italy. In Italy he was again mentioned in despatches, and he was appointed M.B.E. in 1944. For the past two years Dr. Robertson has been assistant medical officer at the East Sussex Mental Hospital.

Tribute to Dr. George Buchan

On his retirement after 35 years as M.O.H. for Willesden, Dr. George Buchan has been made an honorary fellow of the Society of Medical Officers of Health, and with Mrs. Buchan and his daughter he was entertained to luncheon on May 16.

Sir Allen Daley, the president, said that nobody had done more for the society; its mainstay for nearly 40 years, he had been very largely responsible for its growth in numbers, prestige, and financial stability. "But today," said Sir Allen, "we pay tribute to George our friend and companion who holds a lasting place in our affections." Dr. James Fenton said that Dr. Buchan had at all times sacrificed himself and his leisure for the public-health services, and had left his mark on public health. Sir George Elliston spoke as the former secretary who had borne the brunt of his untiring energy, and Dr. Frank Gray described him as "a champion of the depressed classes" who had done much to bind important sections of the profession together. Sir Wilson Jameson declared that "George Buchan has never undertaken to do anything that he didn't do well, and that he didn't do in the time he said." He left Willesden having established a set of personal health services which were the envy of the rest of the country.

In reply, Dr. Buchan said that throughout his career in public health he had believed in the value of the work—though good work was slow work and its recognition was likewise slow. The M.O.H., he thought, ought ideally to have the following qualities: he should be a man of the world and cultivate knowledge, sympathy, and understanding; he should be a faithful servant of his local authority; he should have a sense of fairness to his profession; he should not try to be all things to all men; he must learn how to handle his staff politely but firmly; and before pursuing any proposition he must assure himself of its soundness. The question of the future of public health was difficult to answer but it behoved everyone to make the best of the National Health Service Act, and there was no reason why we should not ultimately have the best health service of any nation.

Appointments

ANDERSON, D. E. W., M.R.C.S., D.P.M.: first asst. M.O., St. Lawrence's Hospital, Caterham.
BROWN, ALEXANDER, M.B., D.P.H.: asst. M.O.H., Walsall.
CHITTY, E. C., M.C., M.B. Aberd., F.R.C.S.E.: senior resident surgeon, St. Stephen's Hospital, L.C.C.
DOBSON, S. C., B.M. Oxfd: asst. pathologist, St. Mary Abbots group laboratory, L.C.C.
ELLIOTT, C. C., M.D.: asst. school M.O., Cornwall.
FERGUSON, MALCOLM, M.B. Durh., D.O.M.S.: ophthalmologist, Sheffield Education Committee.
GREEN, R. D., M.D. Lond., M.R.C.P.: deputy medical superintendent, Paddington Hospital.
HOLLINGSWORTH, GEOFFREY, M.B. Edin., D.R.C.O.G., D.M.R.: radiodiagnostician, Northampton General Hospital.
KITCAT, C. DE W., M.R.C.S.: chief county tuberculosis officer, Somerset.
MOHUN, A. F., M.B. Lond.: asst. pathologist, Archway group laboratory, L.C.C.
PECKAR, V. G., M.B. Lond.: radiodiagnostician, Lambeth Hospital, and St. Charles' Hospital, L.C.C.
PONIEDEL, CLARENCE, M.B. Leeds: clinical tuberculosis officer, Leeds.
ROSS, G. M., M.B. Edin., D.M.R.: asst. radiodiagnostician, Hammersmith Hospital.
SHARKEY, JOSEPH, M.D. N.U.I.: deputy medical superintende Northern Hospital, L.C.C.
STALLWORTHY, K. R., M.B. N.Z., D.P.M.: asst. physician, St. Jan Hospital, Portsmouth.
THOMAS, R. G., M.B. Lond., F.R.C.S.E.: deputy medical superint dent, Queen Mary's Hospital for Children, Carshalton.
THROWER, A. L., M.B. Lond.: asst. M.O., school health servi L.C.C.
WEIL-MALHERBE, H., M.D. Heidelberg, D.SC. Durh.: director research, Runwell Hospital, Wickford, Essex.
WILLIAMS, D. I., M.B. Lond., M.R.C.P.: asst. physician, skin depa ment, King's College Hospital, London.

Royal Liverpool Children's Hospital:

HALL, MURIEL, M.D. Lpool: medical psychologist.
HAY, JANNETT, M.D. Lpool: dermatologist.

Kingston-upon-Hull Health Department:

CAMPBELL, M. S., M.B. Lond., F.R.C.S.E.: senior chief asst. surgery, Beverley Road Hospital.
COATES, J. C., M.B. Leeds, F.R.C.S.: senior chief asst. in surge Anlaby Road Hospital.
GROVES, CHARLES, M.B. Edin.: senior chief asst. in medici Anlaby Road Hospital.

Colonial Medical Service:

ADAMSON, P. B., M.B. Lond.: M.O. (pathologist), Briti Somaliland.
ALDERDICE, A. A., M.B. Sydney, M.R.C.P.: M.O., grade A (phy cian), Trinidad.
ALLERHAND, MAKSYMILIAN, M.D. Lwow: M.O., St. Lucia, Win ward Islands.
BYRNE, A. A., M.C., L.R.C.P.I.: health officer, Malaya.
CAMPBELL, N. G. D., B.M. Oxfd: M.O., Sierra Leone.
DOMAINGUE, F. G., M.B. Lond.: M.O., Mauritius.
GILMORE, T. J., M.R.C.S.: M.O., Falkland Islands.
HUDD, H. R., M.B. Wales: M.O., Tanganyika.
HUDSON, E. G., M.R.C.S.: M.O., anæsthetist, Malaya.
MCCLELLAND, R. S., M.B. Belf.: M.O., Northern Rhodesia.
ROCHESTER, W. R., M.B. Durh.: M.O., Sierra Leone.
WYLIE, H. W., M.B. Manc.: M.O., North Borneo.

Births, Marriages, and Deaths

BIRTHS

BURN.—On April 14, at Cleethorpes, the wife of Dr. J. K. Burn—a son.
CRAIG.—On April 1, the wife of Dr. N. S. Craig—twins (daught and son).
DAY.—On May 6, in London, the wife of Dr. F. M. Day—a daught
FRASER.—On May 15, in London, the wife of Mr. Donald Fras F.R.C.S.—a son.
HALL.—On May 16, at Sutton, Surrey, the wife of Dr. G. F. Hall—a son.
JENKS.—On May 9, in London, the wife of Dr. M. O. Jenks— daughter.
LONGRIDGE.—On May 14, at Exeter, the wife of Mr. Davi Longridge, F.R.C.S.E.—a son.
MACMANUS.—On May 14, the wife of Dr. Niall MacManus—a so
MILLER.—On May 15, at Godalming, the wife of Major J. E. Mille M.C., R.A.M.C.—a son.
REYNARD.—On May 9, at Oxford, the wife of Dr. W. A. B. Reyna —a son.
ROSSITER.—On April 17, at London, Canada, to Dr. Helen an Prof. R. J. Rossiter—a son.
SMITH.—On May 12, at Glasgow, the wife of Dr. John Smith—a so
TALLACK.—On May 5, at Zanzibar, the wife of Dr. R. J. K. Tallac —a daughter.

MARRIAGES

CHASE—PITCHFORTH.—On May 17, at Powerstock, Anthony Chase, M.B., to Jean Pitchforth, S.R.N.
CROOK—BATTEN.—On May 8, in London, Anthony Crook, M.C., major R.A.M.C., to Frances Eleanor Daphne Batten.
STANLEY—GENDLE.—On May 15, at Exeter, Ernest Gerald Stanley, F.R.C.S., to Dorothy Gendle.

DEATHS

HOPKINS.—On May 16, at Cambridge, Sir Frederick Gowland Hopkins, O.M., F.R.C.P., F.R.S., aged 85.
PEARSON.—On May 13, Charles Yelverton Pearson, M.D. N.U.I., F.R.C.S., aged 80.

GROUP TECHNIQUES IN A TRANSITIONAL COMMUNITY

A. T. M. Wilson
M.D. Glasg.
LATE LIEUT.-COLONEL R.A.M.C.

Martin Doyle
M.R.C.S.
LATE MAJOR R.A.M.C.

John Kelnar
M.R.C.S.
LATE LIEUT.-COLONEL R.A.M.C.

Late in 1941 people with special experience began to draw attention to the problems of repatriated prisoners-of-war, who then numbered over 100,000. In 1942 repatriated medical officers began to express views on this matter. Particular interest was aroused by an article by Philip Newman (1944) on his own experience before and after repatriation.

The problems presented by return from Stalag and Oflag emerged within the Army in the ordinary run of everyday work, first, as a result of the high invaliding-rate among repatriated officers who had been back to duty for some months, and secondly, through disciplinary difficulties encountered in repatriated soldiers with previously outstanding military records.

Evolution of Civil Resettlement

(A. T. M. W.)

In 1942, as a first technical step, groups of repatriates were seen by Army psychiatrists on repatriation and 3–6 months after their return to service in this country. In 1943 considerable light was thrown on the deeper psychological background by Major W. R. Bion, R.A.M.C., attached to a special unit set up to offer advice to repatriated officers on military re-employment and retraining. At this time, too, an experimental scheme for the reorientation of repatriated medical personnel was designed by psychiatrists and implemented under medical control. Some time later authority was given for the formation of a small pilot unit which would concentrate exclusively on the resettlement of repatriates leaving the Army for civil life. Finally a Civil Resettlement Planning Headquarters was set up in April, 1945, and by January, 1946, it had become an executive body with twenty regional civil resettlement units (C.R.U.), each capable of taking some 250 repatriated prisoners-of-war for a period varying from a few days to three months, and averaging between four and five weeks (Wilson 1946).

The repatriated officers and men who attend these C.R.U.'s do so as volunteers, and the numbers in which they have volunteered have exceeded what was anticipated. It is not easy to explain this on any other basis than the reality of the repatriate's psychological need. The satisfaction of this need was made possible by the fact that, from the beginning, the problems were elucidated by the help of repatriates, particularly former men of confidence. As an important matter of policy, repatriates have participated throughout in studying their problems, devising methods to deal with them, and running the initial pilot and working units. Without this full participation, from the beginning, of the repatriates themselves, it would have been impossible for these men to overcome a suspicion of the Army and its intentions, which, in soldiers, is partly of historical origin and partly the result of expatriation. In men who have been prisoners-of-war there is an additional difficulty arising from the attitude towards authority forced on them by their exile in the prison camp.

Though men who have been prisoners-of-war may have difficulties resulting from their special experience, their problems show little essential difference from those of other repatriated Servicemen. Expatriation over eighteen months is, by itself, an extremely trying affair, and often a traumatic experience. The significance of this particular period of time was demonstrated by some work done by Major S. Truelove and Major R. Bennett in assessing differential morbidity and other rates in troops overseas, particularly in relation to malaria, venereal disease, and other disorders in which morale played a large part. Expatriation for that period produces acute problems of isolation and frustration, and of mistrust and longing in relation to the home community; against these feelings, expatriates of necessity develop defensive frames of mind.

For these reasons, return home, the need for remaking social relations, and particularly the reintegration of the war-time split family, make severe demands not only on the returning father but also on his wife and children, who have complementary problems of their own. Resettlement therefore involves mutual adjustments between the home community and the returning Service groups.

The steps by which the problem of resettlement emerged and was tackled within the Army were as follows:

(1) Repatriation of prisoners-of-war provided both within and without the Army a problem which was anticipated but not fully allowed for because of the widespread double-edged attitude towards these men.

(2) The problem could not be solved by the capacity for readaptation of the repatriates. Nor could it be solved by the usual medical or administrative actions. It was therefore referred for specialist psychiatric consideration.

(3) Within the field of military psychiatry and psychology fuller diagnosis of the problem was undertaken.

(4) This finally led, still under technical control, to the formation of a pilot therapeutic unit, which provided basic data for the planning staff for a larger organisation.

(5) Control of this organisation reverted to non-technical military authorities, who were, however, advised by psychiatrists and psychologists.

Thus the problem was originally non-medical; it was next referred to psychiatrists, and finally the treatment was carried out by non-specialist personnel under specialist advice. This situation is reflected in group therapy, where an emotional problem is raised in, and discussed by, the group as far as possible, and is then interpreted by a psychiatric group member and returned to the group for further working out and assimilation.

CIVIL RESETTLEMENT UNITS

The *staff* of the civil resettlement organisation was specially selected—as far as possible by technical methods—since the C.R.U. must necessarily work by methods which impose a severe strain on the authoritarian. The best education for the staff was to meet repatriates and discuss their problems with them. The units were formed by budding from the initial pilot unit, and so achieved some integration of policy and method. In setting up a new unit it was necessary to make certain that relations with the neighbouring civilian community were established in such a way that the unit was regarded as an organ of the community as well as of the Army. This was achieved on a basis of sociological planning and not merely through good will.

The staff of the C.R.U. consists, on the one hand, of a central coordinating group, a commanding officer, a second-in-command, and so on, and, on the other, of officers who are case workers. The latter group consists, first, of four syndicate officers, selected regimental officers, each of whom acts as a parent to some sixty men, of whom fifteen arrive each week from a total weekly intake of sixty. Secondly, the C.R.U. has five specialist officers: a vocational officer (with a staff of vocational N.C.O.'s), a Ministry of Labour liaison officer, more recently a Red Cross liaison officer, a professional woman social worker, a technical officer in charge of workshops, and one or, in some cases, two medical officers. It has not been possible to provide all the units with resident psychiatrists.

Atmosphere.—A C.R.U. is a mixed community where more than half the permanent staff members are A.T.S. The atmosphere is designed to encourage initiative, spontaneity, and the ventilation of personal problems,

would supplant the democratic atmosphere essential to the scheme. The recognition by the neurotic element of the effect they were producing on the rest of the community solved the immediate social problem. Their altered attitude and behaviour became reflected in the unit as a whole, which was now not only tolerant of the "bad boys" but also took up a rather protective attitude, removing them from public places if drunk and likely to become a nuisance, and so shielding them and the unit as a whole from the outside world.

Practically no further difficulty was experienced in disciplinary matters after this showdown; nor has one arisen later with similar intensity at any of the other C.R.U.'s subsequently opened. The solution of this single "psychiatric event" was important not only for the community but also for the growth of the whole scheme. So far as the psychiatrist was concerned, it brought him full community status, and his functional rôle became fully established; his services were sought as a valued aid to resettlement instead of being the last resort of a desperate authority. He emerged from his confinement into the general life of the community, taking a natural part in interviewing, discussion groups, or the highly important casual contacts that took place in the N.A.A.F.I., bar, grounds, or corridors, or at the dances. The staff conferences and informal discussions provided a rich channel of communication with the administration and other specialists.

The increasing rate of the demand for psychiatric help is shown by the following figures: during the first month about 5% of the repatriates were seen, all referred through a medical or other officer; whereas in the third and fourth months some 60% were spontaneously seeking advice.

Psychiatric Methods in a C.R.U.

(J. K.)

It is my practice to make contact with every repatriate within a week of his arrival by meeting each syndicate group of fifteen for an introductory group discussion. At this discussion—in contrast to those which I shall describe later—I suggest the theme to be discussed. My favourite questions are, "What do you think resettlement is for?" and "If you were provided with a building and equipment for a C.R.U., how would you plan it and run it, and what would you put into it to help you in your resettlement?" I find this discussion instructive in indicating what problems of resettlement are uppermost in the mind of the repatriate, in that what he puts or asks for in a C.R.U. naturally points to his needs. In other words, this discussion can be used for group diagnosis or screening, which becomes, in psychological terms, a *social projection technique* simultaneously diagnostic and therapeutic; and it is well worth while, in observing and listening to such a discussion, to attempt to forecast which men will, in all likelihood, require further psychological help at a later stage.

After a month at the C.R.U., spent in "establishing my practice," I found that I was seeing, in my psychiatric capacity, about 15% of the intake of other ranks, and about 25% of the officer intake, figures which remained fairly constant for a period, but recently have been rising again considerably. Of the other ranks two-thirds are referred from other members of the staff (medical officer, vocational officer, social worker, and syndicate officer) and about a third come spontaneously. Officers invariably come spontaneously. This relatively large and increasing proportion of both men and officers who come spontaneously is significant. It indicates that, in the C.R.U., a psychiatrist is certainly not a frightening object but a benevolent figure who will understand the mental suffering of which one is perhaps a little ashamed. It indicates also that a considerable proportion of repatriates have insight into the psychological nature of their resettlement difficulties.

PERSONAL INTERVIEWS

Every man who comes to the psychiatrist is seen individually at least once or twice to enable the psychiatrist to get a general picture of the man's background, besides the story of his particular needs. At these individual interviews I usually explain briefly the nature of the man's symptoms and assign him to a group, unless he makes it clear that he will talk only privately, in itself often a significant diagnostic pointer. Unless a man is seen individually at first he may not be ready to accept the idea of being treated in a group, and the personal interview has the inestimable value that the repatriate is made to feel that side by side with the requirements of group therapy his individuality is being respected. No matter how many individual interviews the psychiatrist may previously have had with the repatriate, the subsequent group situation will invariably show up aspects of the case which are new and may even prove to be its most significant features.

GROUP DISCUSSIONS

As regards both the underlying psychological problems involved in resettlement and the general setting of the C.R.U., group therapeutic discussion is the psychiatric method of preference. I have found the optimal number for a group to be from eight to ten men, and that the only important factor to be borne in mind in the selection of its members is to avoid too great a scatter of intelligence levels; otherwise men of low intelligence tend to be browbeaten by the more intelligent members and thereby discouraged from attending. Nowadays three therapeutic group discussions—besides the screening—are held each week, each lasting about $1^1/_2$ hours, and themes being invariably selected by the group.

So far as the psychiatrist is concerned, the principles of the analytic approach are used throughout; the men are told that they can bring up anything they wish, that they need not stick to any particular subject, and that they should continue expressing any theme which comes up in their minds. Sometimes it is explained how this helps them see the nature of their difficulties better, but just as often the group can be left to discover this for itself. Once the discussion is in full swing, it is best for the psychiatrist to recede somewhat into the background, to observe the nature of the interpersonal relationships and to note intragroup tensions which appear. But this is not to say that the psychiatrist removes himself from the picture; on the contrary, he is a *member*, as well as being an observer, of the group, and must choose the right moment to penetrate below the surface, take the unconscious dynamics of the group situation into account, and bring them to light in the interpretations he offers. In this way the group is brought up against its own resistances and defences and makes its difficulties manifest and conscious.

Nothing brings out the real difficulties which repatriates face in their resettlement so well as the material they offer in group discussion. No matter what clinical symptom brings a repatriate for consultation—nervousness, insomnia, or inability to mix with people—such symptoms are but the manifest signs of basic psychological difficulties related to "resocialisation." It is instructive to hear a man, who during the individual interview had complained of irritability or depression, express in the group a most vehement anger and mistrust of authority, and a cynicism and bitterness about life as he has found it since his return. Underlying the repatriate's symptoms is the complaint that the world to which he has come back is hostile and violent, where little that is done is genuine or sincere. He feels that his world has let him down, and that his sense of confidence and security has been undermined. His defence against consequent feelings of guilt and frustration is an embittered withdrawal from social relationships, which we see as apathy and depression.

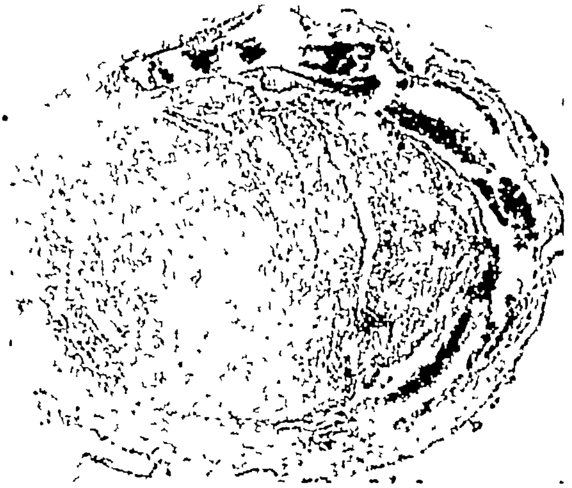


Fig. 3—Left middle cerebral artery; abscess in muscular coat and infected thrombus (case 3).

Destruction of muscular coat and abscess formation in three-quarters of its circumference (fig. 3). Elastic membrane stretched and torn in area corresponding to infiltration of muscular layer, and endothelial lining absent. Lumen of artery obliterated by fibrin clot except a small area corresponding to better-preserved part of wall of artery.

. Intense polymorph round-cell infiltration with partly degenerated cells in region of thrombus attached to diseased wall of artery; round-cell infiltration decreased markedly towards centre of thrombus.

Right middle cerebral artery showed thrombosis in a stage of advanced recanalisation at level of bifurcation of artery and extending into ramus horizontalis posterior. Muscular layer of ramus horizontalis very thin and completely defective in a circumscript area. Moderate round-cell infiltration of muscular layer (fig. 4).

Summary of Histological Findings.—The site of the infection of cerebral arteries in all 3 cases was the fork of branching vessels or its immediate neighbourhood. The anterior cerebral artery was involved once, the middle cerebral artery three times (fig. 5). Inflammation was greatest in the muscular coat amounting to abscess formation. There was incipient cylindrical aneurysm and impending or early rupture. The occlusion of infected arteries was due to thrombosis. The histological picture indicated a highly acute infective process in 2 cases and a subacute to chronic inflammation in the third case. The possibility of recanalisation of an infected thrombus situated in a cerebral artery was illustrated by the third case. Evidence of systemic arterial disease was absent in all three cases.

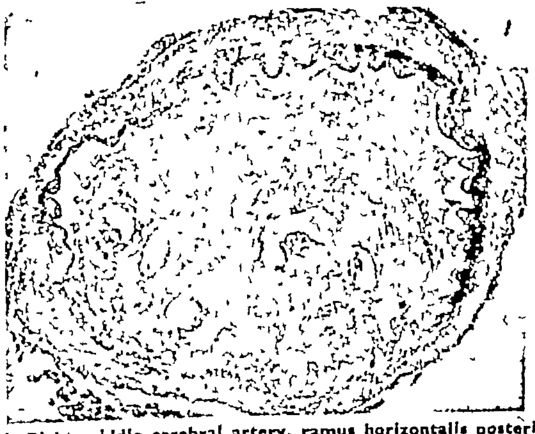

Fig. 4—Right middle cerebral artery, ramus horizontalis posterior; defect and thinning of muscular layer and recanalised thrombus case 3).

DISCUSSION

The site of the arterial lesions and the absence of systemic involvement of arteries indicated embolic infective particles as the cause of the thrombosis. For that reason and because of the prominent involvement of the media layer and practically normal adventitial layer it was thought that periarteritis nodosa could be excluded.

There was no evidence of a compact embolus occluding the infected arteries, the final obstruction being due to secondary thrombosis; this was especially well seen in case 3. It was thought that the arterial emboli were of minute dimensions, in themselves unable to occlude the arteries involved.

The usual sources of infective emboli in cerebral arteries, infective endocarditis, suppurative lung lesions, and lesions of the systemic circulation in the presence of a patent foramen ovale were not found. It was concluded that the infective material must have passed the capillary filter of the lung. Probable primary foci have been recorded in 2 of these cases—chronic tonsillitis and chronic otitis media. It remains a matter of speculation to decide if the original emboli were purely bacterial, suggesting a low-grade septicæmia or pyæmia; minute particles from an infective thrombus in the systemic circulation; or an intermediate capillary thrombus in the lung. The site of the embolic lesions suggests that the embolus was of microscopical size in two dimensions but possibly filiform.

In 3 out of 7 cases of cerebral softening in young adults, the cause has been shown to be embolism of cerebral arteries by infective particles from the distal systemic circulation in the absence of a patent foramen ovale. On this evidence it seems probable that this mechanism, usually regarded as exceptional, is responsible for a considerable percentage of cases of cerebral softening in young adults.

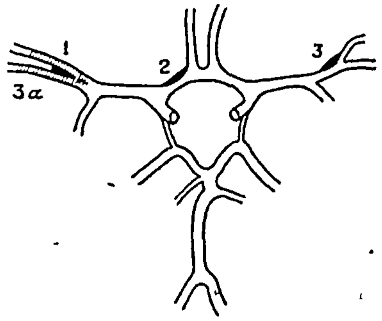

Fig. 5—Circle of Willis: black marks indicate sites of infection (cases 1, 2, and 3); shaded area 3a indicates site of recanalised thrombus (case 3).

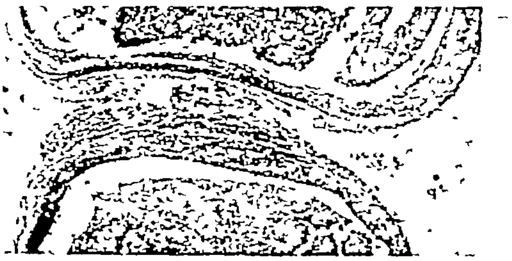
The explanation of embolism of cerebral arteries through a patent foramen ovale has to overcome the difficulty of explaining how the embolic particle passes from the low-pressured right atrium into the high-pressured left atrium. One might consider that some of the cases of so-called paradoxical embolism in the presence of a patent but not dehiscent foramen ovale are due to the same mechanism as the cases described here.

One might also consider the possibility that certain "congenital" aneurysms of cerebral arteries are of infective origin, an interpretation suggested by Cushing. In our series 1 case of aneurysm was observed, but unfortunately the aneurysm was not examined histologically. The aneurysm, as big as a pea, was situated at the branching of the ramus corporis callosi from the trunk of the anterior cerebral artery; the aneurysm was thrombosed, but there was no thrombosis of the artery itself, and multiple embolic foci were found in the cerebral cortex and in the genu corporis callosi, finally producing a communication of the lateral ventricle with the subarachnoidal space.

It is of interest that the fatal stroke took place only when the thrombosis of the trunk of the middle cerebral artery had occluded the rami perforantes. The right-

Immediately proximal to branching of artery into truncus mmunis and ramus horizontalis posterior, polymorphs, rtly degenerated, appeared in centre of thrombus. At el of fork of branching arteries much polymorph round-l infiltration was seen in fork and spreading along circum-ence of arteries (fig. 1). Round-cell infiltration had its eatest intensity in muscular layer, with extensive destruc-n of muscle bundles and formation of minute abscesses. timal layer of fork and of branching arteries showed loss f endothelial lining; internal elastic layer was stretched and rn; both arteries showed signs of impending rupture.



g. 1—Fork of right middle cerebral artery; polymorph round-cell infiltration of media and destruction of muscular coat (case 1).

Examination of brain at various levels showed no other idence of vascular disease.

Case 2.—A sweeper, aged 20, was found lying unconscious ı his billet and brought to hospital on April 2, 1945. The llowing history was given by his room-mate. Patient had omplained of abdominal pain after dinner, vomited twice, and assed three stools up to midnight. *At midnight, trying to* o to the lavatory, he had fallen from his cot. After that he ad been peculiar and unable to answer questions.

On admission 13 hours later patient showed a typical left emiplegia with involvement of face. There was no evidence f head injury. He could answer questions and asked for ater. Pupils equal and reacted to light, though sluggishly. Limbs of left side flaccid; blood-pressure 108/70.

Three hours later patient was improving and showed more nterest in his surroundings. He had no fever, and his pulse as good. Total white-cell count was 18,000 (polymorphs 5%, lymphocytes 18%, monocytes 7%). Blood films egative for malarial parasites.

April 3: Patient's condition was worse in the morning, nd he became unconscious; right pupil dilated and fixed, eft pupil of normal size and reacting to light. Right plantar eflex *extensor; right ankle clonus.*

Lumbar puncture: 8 c.cm. of fluid, clear and under slightly ncreased pressure, was removed. Cells and protein normal. lbumin in urine.

April 4: Patient's condition deteriorated. Temperature 101·8°F, pulse-rate 150, respirations 36 per min. Right plantar reflex absent; no clonus on right side. Blood-pressure 126/84. Left hemiplegia present as before. Coma deepened, and patient died on April 5, at 3 A.M.

Necropsy (six hours after death): The body was that of a young Indian male; turgor somewhat reduced; rigor mortis present.

Skull: Dura mater tense; middle-ear cavities normal; venous sinuses patent.

Brain and meninges: Hyperæmic congestion of meningeal veins of right hemisphere; gyri of right hemisphere flattened; moderate right-sided tentorial pressure cone. Extensive red thrombosis of trunks of right middle cerebral and right anterior cerebral arteries.

Frontal sections of brain showed œdematous swelling of he right hemisphere and early softening in white matter of the frontoparietal lobe and of temporal pole. Right half of circle of Willis and left posterior cerebral artery normal.

Microscopically, right middle cerebral artery greatly distended, with lumen obstructed by red thrombosis; no evidence of atherosclerosis, syphilis, or mycotic arteritis. Right anterior cerebral artery showed at level of origin from internal carotid artery, circumscript polymorph round-cell infiltration of muscular coat, with complete destruction of muscle bundles, intimal layer showed loss of endothelial cells; elastic membrane stretched and torn (fig. 2). The artery was greatly distended and lumen obstructed by predominantly red thrombus formation. Partly degenerated polymorphonuclear round cells seen in thrombus and prominent opposite infected area of wall of artery. Sections of the artery distal to this level showed severe dilatation and obstruction of lumen by red thrombosis. Sections of the brain taken at various levels showed no evidence of vascular disease.

Other organs: Left *tonsil* enlarged, with retention cysts (a smear from one of the cysts showed degenerating leucocytes and streptococci in short chains). *Lungs* showed scattered areas of atelectasis and localised adhesions over left upper lobe. *Heart* of normal size and consistence; no evidence of valvular disease. Foramen ovale and septum membranaceum closed. Aorta and coronary arteries normal.

No gross pathological changes were seen in abdominal cavity; spleen of normal size and consistence. Slight dystopia of the left kidney pelvis, with scanty ecchymosis in mucosa. No evidence of thrombosis of hæmorrhoidal veins.

Case 3.—A sepoy, aged 20, had had a fit at the railway station and been brought to hospital on June 11, 1945. He gave a history of suppuration of one ear for a year. He had also had occasional "fits" for a year. Patient became unconscious soon after admission.

Blood films were negative for malarial parasites. First mepacrine was given *intramuscularly and quinine intravenously.* Patient remained unconscious and had frequent convulsive attacks.

White count was 18,000 cells per c.mm. Lumbar puncture was done and 8 cells were found in cerebrospinal fluid. Routine examination of urine gave negative results. Patient then received 'Soluseptasine.'

June 13: Temperature 104°F (previously 107°F), pulse-rate 145, respirations 36 per min. Left tympanic membrane was perforated, and fluid was visible in middle-ear cavity. Dullness with diminished breath sounds at left base. Left pupil pin-point, right $^1/_4$ in., pupils fixed. Reflexes and tone in left arm normal. Right arm could not be examined owing to intravenous drip. Abdominal reflexes absent. Tone of right leg increased. Knee-jerks absent, ankle-jerks present. Plantar reflexes extensor. Patient died during a second lumbar puncture.

Necropsy: Inflammatory œdema and consolidation of left lung; trachea filled with froth; heart flabby but no evidence of valvular disease; foramen ovale closed; aorta and coronary arteries normal. Meninges congested; no evidence of thrombosis of venous sinuses.

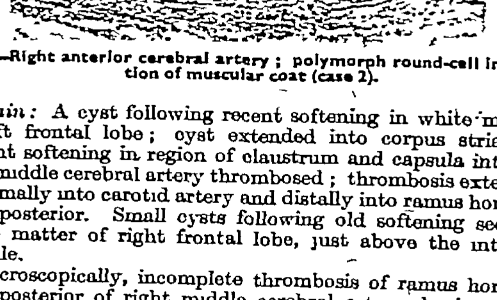


Fig. 2—Right anterior cerebral artery; polymorph round-cell infiltration of muscular coat (case 2).

Brain: A cyst following recent softening in white matter of left frontal lobe; cyst extended into corpus striatum. Recent softening in region of claustrum and capsula interna. Left middle cerebral artery thrombosed; thrombosis extended proximally into carotid artery and distally into ramus horizontalis posterior. Small cysts following old softening seen in white matter of right frontal lobe, just above the internal capsule.

Macroscopically, incomplete thrombosis of ramus horizontalis posterior of right middle cerebral artery, beginning at bifurcation of trunks of right middle cerebral artery.

Microscopically, sections of left frontal lobe showed multiple small foci of cortical and deep softening; softening incomplete, with large gitter cells between better-preserved structures. Numerous calcified nerve-cells in areas near to cortical softening and in places of actual softening. Occipital cortex showed no evidence of vascular disease or thrombosis.

Left middle cerebral artery showed red thrombosis of trunk. Severe mycotic arteritis immediately proximal to bifurcation into truncus communis and ramus horizontalis posterior

SCHEME OF DOSAGE WITH SULPHONAMIDES

—	No. of 0·5 g. tablets				
	1st day	2nd day	3rd day	4th day	5th day
Adults	6, 4, 4, 2	3, 3, 3	2, 2, 2	2, 2, 2	2, 2, 2

3 months ..	¼, ¼, ¼, ¼	¼, ¼, ¼	¼, ¼	¼, ¼	..

No known ill effects were experienced from this intensive initial therapy, except that 2 babies died about seven days afterwards from complete digestive failure, passing undigested stools. There were 4 other known cases of this digestive derangement, which may be due to sulphanilamide poisoning. These infants were invariably under a year old, and the history in each case was of passing undigested milk stools for about a week after treatment ceased, until death supervened. Loss of weight, in the cases noted, was rapid.

Only sulphanilamide (sometimes as 'Streptocide') and sulphapyridine were used in this series. Of these, sulphanilamide is definitely the drug of choice and was used in over 75% of the cases treated. This drug gives a better response, is better tolerated, and has the highest cure-rate. Sulphapyridine sometimes left the patient rather weak and mentally depressed for a few days.

No cases of suppression or of hæmaturia were seen in the 600 hospital cases, or reported from the treatment camps. (There was 1 possible case of suppression of urine in the previous epidemic of 850 cases.)

Sulphanilamide as a rule restored the temperature to normal within 24 hours. With sulphapyridine this was not usually accomplished before 24–30 hours.

Sulphathiazole was used only in 1 severe case in which the infection did not respond to sulphanilamide or sulphapyridine. In all, 54 g. of these three sulphonamide compounds was given *in six days. Sulphathiazole rapidly reduced the pyrexia,* and after a long convalescence the only sequelæ were a mild ptosis of one eyelid and a small corneal opacity following a corneal ulcer which developed during the acute stage.

SOME COMPLICATING FACTORS

The bulk of cases were in the age-group 1–25. Two patients aged about 60 both died. Those who developed a squint or ptosis usually did not die.

Paralysis of the soft palate and fauces was fairly common and usually of very early onset. In such cases the drug was given by intramuscular injection (sulphapyridine soluble, 1–2 g., repeated as necessary, or sulphanilamide, or sulphapyridine suspension, 3 g. in 10 c.cm. of sterile distilled water, repeated in three hours if necessary). Usually patients were sufficiently recovered within twelve hours to be able to swallow.

Herpes labialis was noted in about 5% of cases. A few cases were seen in which the herpes extended over the whole face.

In very severe cases an acidosis often developed within thirty-six hours of the onset; this was treated with mist. sod. bicarb. and glucose.

Of the 600 hospital patients 6 were admitted with the full signs and symptoms of meningitis but without fever. The following is a striking example:

Case 1.—A schoolboy, aged 15, was writing, and when he tried to look down from the blackboard to his paper he found that his neck was slightly stiff and painful. He had a headache. When seen 15 min. later his neck was as stiff as a board. His temperature was normal. Treatment was begun at once and within two hours his temperature rose to 99·8°F—not to 103–104°F as with the normal *febrile* admission. The neck rigidity lessened but was present for four days.

In many cases there was a residual stiff neck following five days' treatment, but this was not an adverse sign *if the temperature was normal,* for the neck rigidity cleared within a few days without further treatment.

Patients with a concomitant disease—e.g., trypanosomiasis, advanced yaws, and tuberculosis—did not resist the disease well. Abortion was fairly common in pregnant women, and the mortality among them was high.

In the few cases in which lumbar puncture was done soon after the start of treatment the cerebrospinal fluid (C.S.F.) contained numerous polymorphs but no organisms. The shortest period between the start of treatment and lumbar puncture was three hours.

SEQUELÆ

The following sequelæ were seen

600 Hospital cases

Bilateral effusion in knee-joints	1	
Unilateral effusion in knee-joints	4	
,, ,, elbow-joints	1	
Spastic paraplegia	1	
Mild dementia a month later (recovered)	1	
Infant deaths from intestinal disorder (a week later)	2	
Reinfection	3	
Total	13	(1·17%)

Isolation camps

Bilateral effusion in knee-joints	2
Paralysis of left arm	1
Paralysis of right leg	1
Deafness and dumbness (one subsequently died) ..	2
Hydrocephalus, 18 months child (3 months after discharge)	1
Infant deaths from intestinal disorder (a week later)	4
Reinfection	1
Relapse	1

(Incomplete)

B. B. Waddy, who has since trekked in part of the area *involved, believes that the incidence of residual* intracranial lesions, from persistent headache to severe paraplegia, is in the region of 1%.

SECOND ATTACKS

Of the 6 cases described below no. 2 is regarded as a relapse, while it is thought that the other 5 suffered from cerebrospinal fever. Pneumococcal meningitis is a possibility; but in view of the intensity of infection by the meningococcus in the area, and the subsequent fairly good response to treatment, it seems probable that the meningococcus was responsible on both occasions.

Case 2.—A girl, aged 3 years, developed meningitis and was treated in a bush camp for four days and discharged cured. She was readmitted six days later but died after the second dose of medicine.

Case 3.—A boy inpatient, aged 16, had almost recovered from a chronic osteomyelitis of tibia. He developed a meningitis of gradual onset, the neck rigidity developing suddenly on the third day. Treatment was commenced on the third day and continued for five days. He was perfectly well and up and about as soon as treatment was finished. Nine days after the completion of treatment he suddenly developed a second attack of meningitis. On this occasion he was severely ill and had to be treated with intramuscular preparations. He subsequently made a normal recovery.

Case 4.—A soldier, aged 10, was admitted with a meningitis of sudden onset. He was treated for six days. Pending the *grant of sick-leave* he remained in hospital and was perfectly well. Ten days after treatment ended he again developed a meningitis of sudden onset. He underwent lumbar puncture three hours after the administration of 3 g. of sulphanilamide, but the C.S.F., although packed with polymorphs, contained no organisms. He was dangerously ill for four days, though his temperature returned to normal on the third morning. He subsequently recovered.

Case 5.—A schoolboy, aged 6, was admitted with a meningitis of sudden onset. The temperature of 104°F returned to normal in less than twenty-four hours. He was treated for five days and returned to school. Twenty-three *days after* the completion of treatment he was readmitted ided occlusion of the ramus horizontalis posterior of the middle cerebral artery produced only minor foci of oftening. Comparison of our material with the cases f the Neurological Centre (British Troops), India Command, shows that out of 12 cases observed there were only 3 in the age-group below thirty-five years, and only 1 below thirty years. None of these were fatal. Non-fatal cases of cerebral occlusion in young Indian adults in the absence of syphilis are said to be common, but subacute bacterial endocarditis is rare in Indians. Only further examination of non-Indian cases will show if the mechanism of cerebral occlusion, described here as not uncommon in Indian troops, is of the same importance in other populations.

SUMMARY

Of 7 fatal cases of cerebral thrombosis in young Indian adults 3 were due to thrombosis of infected cerebral arteries.

Infective endocarditis, suppurative lung lesions, and a patent foramen ovale were absent from all 3 cases.

For this reason these cases were interpreted as instances of transpulmonary embolism of minute particles from foci in the systemic circulation.

It is thought that, contrary to the common belief, this mechanism is responsible for a considerable percentage of cases of cerebral occlusion in young Indian adults.

Its importance for populations other than Indian should be assessed by examination of further material.

I am indebted to the Director of Medical Services, India Command, for permission to publish; Brigadiers D. Denny-Brown, J. F. Fulton, H. K. Goadby, and D. McAlpine, Colonel J. E. Hall, and Lieut.-Colonels H. M. Garland, J. A. Manifold, and W. Aldren Turner for their interest in the work; Prof. Abdul Rahman for permission to use the photomicrographic equipment of the Osmania University, Hyderabad; and Sergeants Gould and Foster for the technical work in histology.

CEREBROSPINAL MENINGITIS IN THE GOLD COAST

A REVIEW OF 9864 CASES

COLONIAL MEDICAL SERVICE

B. B. Waddy
B.M. Oxfd
COLONIAL MEDICAL SERVICE

R. W. Tudor
M.B. Birm.
CAPTAIN R.A.M.C.

During the latter part of the last century there were major epidemics of cerebrospinal meningitis (C.S.M.) in the western province of the Northern Territories of the Gold Coast. These decimated the Lobi population year after year, until the disease died out about 1908. Any patient who survived was, as a result, often deaf, dumb, or permanently demented.

Epidemics of C.S.M. are likely to occur during the dry season, especially when the very dry dust-filled breeze of the *harmattan* blows southward from the Sahara about December and January. This dry atmosphere can cause chapping of the lips; respiratory infections are common. The nights are cold, and this causes the people to sleep indoors, and close together, in their ill-ventilated flat-roofed mud houses. Such conditions are ideal for an increase in the carrier-rate, and a subsequent epidemic.

Small epidemics restarted in this area in 1941, when there were 45 cases. The number rose to 140 in 1943 (with a case-mortality just over 30%) and 850 in 1944. In 1945 there were 9864 cases, with 1057 deaths: this gives a case-mortality of 10·7%, but 286 patients died untreated and in the treated cases it was 8·05%. The mortality figures suggest that in 1945 the virulence of the infection was mild; but this was not so.

In the 1944 epidemic of 850 cases the disease was of medium virulence, cases lasting, earlier on, for twelve hours untreated and, later on, for three or four days. The total case-mortality was 19·3%, against a mortality of 13·4% in the treated cases. Then the disease was new to the present generation. Treatment was usually continued for seven days, adults receiving sulphanilamide 3 g. daily.

In the 1945 epidemic the disease was of far greater virulence, most of the untreated patients dying two to six hours from the onset. A few patients survived up to forty-eight hours, but the mortality among these, although they were treated, was high. Included in our treated mortality figures are almost hopeless cases which received only one treatment, the patients dying within the next two hours.

Sporadic cases are normally expected about January or February, following the *harmattan*, and these may give rise to an epidemic about March, when the dry season, which lasts from September to May, is at its height. In the 1945 epidemic, following the 850 cases of the previous dry season, sporadic cases started as early as the middle of October, 1944; and these gave rise to the present epidemic, which started in earnest on Jan. 1, 1945.

It is well known locally that, with the onset of the rains in mid-April onwards, an epidemic of C.S.M. will slacken and die out. This happened in the 1945 epidemic, although sporadic cases extended further into the wet season than is usually expected. Sporadic cases restarted as early as September, instead of January or February.

The 1945 epidemic extended over approximately 10,000 sq. miles (cf. Wales 7470 sq. miles), and involved a scattered population of about 200,000. Communications and accessibility in the bush are difficult, especially when dealing with a rather primitive population, although Army jeeps greatly overcame these difficulties. As a result exact and scientific data are limited, since the primary concern of all staff involved, both civil and military, was to prevent the epidemic from spreading, and to treat such cases as occurred. Preventive and treatment staff directly concerned numbered 5 Europeans and just over 100 Africans. In view of the vast area to be covered, the number of cases, and the number of staff capable of scientific investigations, it must be appreciated that this article cannot contribute much to bacteriology but is mainly concerned with general observations.

TREATMENT AND ITS RESULTS

In view of the rapidity with which patients died, it was found necessary to increase massively the initial treatment, sulphanilamide or sulphapyridine 8–9 g. being administered during the first nine hours, as against 6 g. in twenty-four hours in the 1944 epidemic, as follows:

	Normal case	*Severe case*
Initial dosage	3 g.	3 g.
3 hours later	2 g.	3 g.
6 " "	2 g.	2 g.
9 " "	1 g.	1 g.
Total	8 g.	9 g.

When a patient was admitted to hospital or isolation camp during the day, this treatment was given with no further administrations until 6 A.M. next day. Subsequent treatment is indicated in the accompanying table. When a patient was admitted during the night, this nine hours' treatment was given, followed directly by the doses recorded in the table. There appears to be no difference in mortality with these two modifications of dosage.

If a severe adult case was sufficiently improved by the second day, it reverted to the normal course of treatment.

together by suture, owing to their friability, especially of the proximal torn fragment.

In these cases it has been the custom to introduce a catheter through the penis to the perineum, and another, via a suprapubic cystotomy, through the prostatic urethra to the perineum. One then cuts down on the perineum and secures the ends of these catheters; and so, by the "railroad" technique, draws the penile catheter up into the bladder, thus bridging the tissue intervening between the torn ends of the urethra, and relying on granulation and fibrous tissue to re-establish a passage between the two ends (fig. 2). It is clearly better, however, to approximate the separated ends of the urethra; and I have successfully accomplished this in three cases.

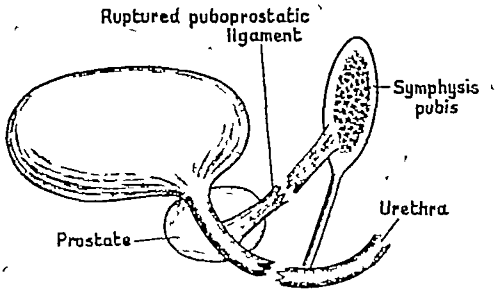

Fig. 1—Rupture of urethra close to prostate, with tearing of puboprostatic ligament and consequent backward displacement of bladder and prostate.

METHOD

A suprapubic cystotomy is performed, through which the bladder wall is inspected and its integrity verified, and a gum-elastic catheter is passed along the urethra from the bladder as far as it will go. With the catheter held in position by an assistant, the patient's legs are held up, and a Foley's catheter is passed down the penile urethra until it meets obstruction. Next, the perineum is opened by a midline incision on to the ends of the two catheters, and these are joined together with a stout silk or thread suture. The gum-elastic catheter is then withdrawn, drawing into the bladder behind it the Foley's catheter. No suture of the perineal wound is necessary, since the parts fall together naturally, and dependent drainage is allowed.

The bag of the Foley's catheter is now inflated with 20 c.cm. of water, and the suprapubic incision is sutured round a suprapubic tube inserted obliquely through the abdominal parietes, as recommended by Riches,[1] to encourage early closing of the suprapubic fistula after the tube is withdrawn, and to avoid osteomyelitis of the pubis, which is liable to develop (as in case 1) when the tube is in contact with that bone. The perivesical tissues are suitably drained if extravasation has taken place.

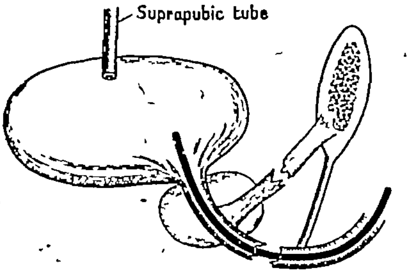

Fig. 2—Usual method of dealing with rupture of urethra, as in fig. 1, by inserting a catheter and relying on granulation tissue and fibrous tissue to bridge the gap.

The divided ends of the urethra are next brought together by applying a continuous traction of 2 lb. to the end of the Foley's catheter via a cord over a pulley at the end of the bed (fig. 3). After a fortnight the Foley's catheter is deflated and withdrawn, and a sound is immediately and very gently passed. This is an anxious moment, but in the cases in which I have done it it has proved perfectly simple.

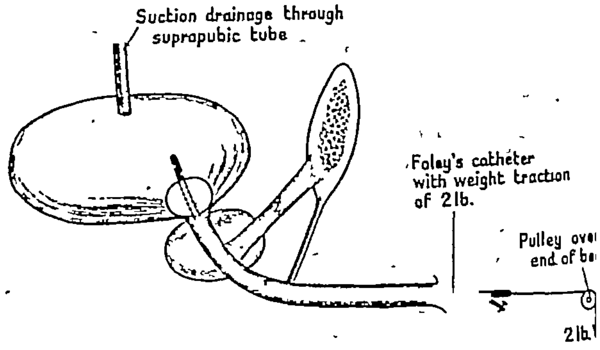
Two or three days later, when the patient starts passing urine, the suprapubic tube is withdrawn, and the fistula is allowed to heal. Sounds are passed wee and then at longer intervals.

CASE-RECORDS

Case 1.—A man, aged 24, was admitted to hospital witl extraperitoneal rupture of the bladder and a dislocat backwards of the bladder and the prostate, with extravasat of urine. Suture of the bladder, *traction of the bladder,* drainage of the perivesical tissues were performed, and penile catheter was removed after fourteen days. Pass of urine per urethram started after two days, and the sup pubic tube was removed. The suprapubic fistula was hea after a further week, but a sinus down to bone persis owing to an osteomyelitis of the pubis, which required rat prolonged treatment. Six months later there was no evide of stricture.

Case 2.—A boy, aged 11, was admitted to hospital witl dislocation of the bladder and prostate backwards, with extravasation. Traction of the bladder was performed, a high suprapubic drainage established. After fourteen de the Foley's catheter was removed, and passage of uri through normal channels started three days later, when t suprapubic tube was removed. After five days the sup pubic wound was dry. Eight months later there was evidence of stricture.

Case 3.—A man, aged 39, as a result of an accident, sustain a fracture of the sacrum, a fracture of the anatomical neck the femur, and a fracture of the acetabulum, all witho displacement. He also suffered a rupture of the urethra at th level of the apex of the prostate with backward dislocation o the bladder. There was no extravasation. Traction of th bladder and high suprapubic drainage was established. Th normal flow of urine occurred in twelve days and he was di in sixteen days. Four months after the accident there was n sign of stricture formation. This case is of interest in that the was no displacement of the bony pelvis, and it would appe that rupture occurred by the shearing force of a violen *sudden acceleration injury,* through being run into from behir by a motor vehicle, having a full bladder at the time.



Suction drainage through suprapubic tube
Foley's catheter with weight traction of 2lb.

2lb.

Fig. 3—Traction on bladder, through catheter, to approximate the tor ends of the urethra.

SUMMARY

The torn ends of a ruptured urethra can be approx mated by applying traction to the bladder throug a Foley's catheter.

Three cases are reported in which this was done succes fully.

There was no sign of stricture 6, 8, and 4 months afte operation.

" . . . The diseases responsible for most sickness and deatl today are *no longer* the infectious diseases such as typhoi fever, tuberculosis, and the acute exanthemas. They ar diseases obscure in origin and chronic in their course, such a the several forms of heart and arterial diseases, diabete cancer, rheumatoid and other forms of arthritis. None of th conventional methods of *preventive* medicine will ward of any of these disorders. The public health officer is learnin that in order to control their ravages—for in the presen state of medical knowledge their *prevention* is still beyond th range of medical science—the most potent weapon is immediat and ready accessibility to medical care, both for diagnosis an treatment."—Dr. ERNEST P. BOAS, *J. Pediat.* 1947, **30**, 478.

[1] Riches, E. W. *Brit. J. Surg.* 1943, 31, 135.

with meningitis. He was slightly more ill on this occasion than before, but made a normal recovery.

Case 6.—A youth, aged 20, developed meningitis and was treated for five days in a bush camp and discharged cured. Nine days later he was readmitted with meningitis, treated for another five days, and recovered.

Case 7.—A girl, aged 3 years, developed meningitis and was treated for four days in a bush camp. She was readmitted eighteen days after the completion of treatment but died on the eighth day of the second attack.

Thus, after a full course of treatment, patients have had a second attack of meningitis after intervals of 6, 9, 9, 10, 18, and 23 days. The second attack has in each case been more severe than the first, although, except fatal cases 2 and 7, they have responded normally to sulphanilamide or to sulphapyridine. The greater severity of the second attack is no doubt due to lowered physical condition. The failure to develop immunity may perhaps be attributed to treatment with sulphonamides. Councilman,[1] in America, reported 5 patients who were reputed to have had C.S.M. twice.

PREVENTION

It is difficult to control the movements of an African community, especially when the area in which they move is large. However, efforts were made in this epidemic to control movements by banning funeral ceremonies, at which as many as 300 natives may attend for two or three ays; closing markets entirely, or after 2 P.M.; and ontrolling foot and lorry travellers, and traders.

Overcrowding and bad housing played their parts in the pread of this epidemic. The people were advised to sleep on the top of their flat-roofed mud houses, but they seldom took this advice. A few villages which were harder hit than others built temporary grass houses.

INITIAL TREATMENT BY NON-MEDICAL PERSONNEL

Owing to the very large area affected, the great number of villages involved, and the fact that deaths took place in 2–6 hours, it was impossible for medical staff to be always on the spot: one member might be looking after 100 sq. miles. It was found that the best plan was to visit the villages surrounding an infected place, and to talk to the chief, explain the sickness to him, and warn him to be on the lookout. Confidence was further gained by giving him a few tablets of a sulphonamide. Literates were supplied with a simple paper on diagnosis, and a chart of dosage. Illiterates were given tablets and told to give one tablet for every "double hand-span" (18 in.) of the patient's height, before sending the patient to the nearest treatment camp. This dose was to be given twice (dose repeated in three hours) if they were far away from the nearest camp.

It is thought that the low mortality of this epidemic is due to (1) the confidence of the people in European medicine acquired in the smaller epidemic of the previous year; (2) increasing this confidence by giving their chiefs a miraculous drug, with the result that cases were early reported to an authority, who not only managed to treat but also forwarded information immediately; and (3) control of movements, funeral ceremonies, markets, and travelling.

CARRIER-RATE

The epidemic slackened considerably towards the middle of April (8000 cases) with the start of the rains. Under 2000 cases occurred in the next two months. Despite war-time commitments the Army managed to lend facilities for bacteriological investigations, which were carried out towards the end of the epidemic. In Wa town (6000 inhabitants) there had been approximately a 2% infection of clinical cases of meningitis between January and April. In July, in 200 persons examined at random, there was a positive carrier-rate of about 6%. The meningococcus was identified as type I.

SUMMARY

In 1945 a Gold Coast district covering some 10,000 sq. miles, with a population of about 200,000, had 9864 cases of cerebrospinal meningitis.

The number of deaths was 1057, giving a case-mortality of 10·7%. In treated cases (including the moribund) the mortality was 8·05%.

As the disease often ran a rapid course, intensive initial treatment with sulphonamides was instituted, 8 or 9 g. being given in the first nine hours.

Sulphanilamide, which was used in over three-quarters of the cases, was better tolerated and gave better results than sulphapyridine.

In 6 cases there was a second attack of cerebrospinal meningitis.

Initial sulphonamide treatment was given successfully in the villages by the native chiefs. This and other measures helped to control the epidemic.

ADDENDUM

A fresh epidemic of meningitis during the dry season of 1945–46 was feared and anticipated by all concerned. A preventive scheme, involving universal sleeping-out and prohibition of overnight travel (both through-traffic and local visits), was therefore designed and put into force from the very beginning of the dry season. It was considered that by the time cases in any number occurred, to indicate the presence of an epidemic, the carrier-rate would be so high that preventive measures would be comparatively ineffective.

In the event, cases of meningitis during the 1945–46 dry season totalled 58, of which 52 were of meningococcal or doubtful origin. It is not possible to estimate to what extent this virtual elimination of the disease was due to (1) preventive measures, (2) possible mass-immunity after the presumably high carrier-rate of the previous year, and (3) climatic factors, chiefly a rather humid period during January, 1946.

In the same district in the recent dry season of 1946–47 there have been 65 cases of meningitis, of which we have no details.

We are indebted to Dr. J. G. S. Turner, acting D.M.S., Gold Coast Medical Service, and Brigadier H. B. F. Dixon, M.C., D.D.M.S., West Africa Command, for permission to publish this paper.

TREATMENT OF RUPTURED URETHRA BY BLADDER TRACTION

PETER MARTIN
M.Chir. Camb.
SURGEON, CHELMSFORD AND ESSEX HOSPITAL

THE problem of traumatic rupture of the urethra has been largely solved by applying one of the first principles of surgical treatment—namely, rest. The flow of urine is diverted through a suprapubic fistula until the torn urethra is united.

If rest to the part is established, and gross sepsis avoided, the urethra will reform and become lined anew with epithelium, provided its torn ends can be approximated. Where such approximation is impossible, healing can only be by granulation tissue, and a fibrous stricture is bound to ensue, with its attendant dangers and tedium, entailing, throughout the rest of the patient's life, periodic dilatation with bougies. Where, for example, fracture of the pelvis has caused rupture at the apex of the prostate, with tearing of the puboprostatic ligaments (fig. 1) and backward dislocation of the bladder and prostate, the ends of the urethra may be found to be more than $1^{1}/_{2}$ in. apart and separated by a mass of hæmorrhagic and lacerated tissue; and, even if they are identified, it is impossible to draw them premenstrual eruptions of acne. The acne was very pronounced when the following period was more excessive than the previous one. All symptoms subsided with lutocyclin, and this is now a very good preventive in gradually diminishing dosage.

Case 4.—Female, aged 36. Periods began at 14. Married when 17. There were six pregnancies during the first nine years of married life, the last being ten years ago. Migraine, lasting seven years, started about three years after this pregnancy. The attacks were severe and frequent, without any definite relation to the menstrual periods, which were normal. Treatment for a retroverted uterus and right-sided salpingitis, and for indigestion, did not affect the migraine; nor did vitamin B_1 given in large doses for pain in the calf muscles (at times very severe), and burning of the soles, of three years' duration. Wassermann reaction and Kahn tests were negative.

She became pregnant again sixteen months ago, and migraine ceased after the fourth month of pregnancy but recurred six months after parturition. The symptoms referred to the legs and stomach also ceased during pregnancy, and reappeared with migraine after parturition. All symptoms have responded to lutocyclin.

RELATION OF SYMPTOMS TO VARIATIONS IN EXCRETION OF ŒSTROGENS AND PROGESTERONE

In these cases a definite relation exists between the attacks of migraine and the time at which the excretion of free œstrogen in the urine would be expected. Thus mid- and pre-menstrual attacks of migraine correspond to the periods when free œstrogen is excreted in the urine. Its disappearance with the progress of pregnancy corresponds to the increased ratio of œstriol to œstrone in the urine, the absence of œstradiol in the blood, and the increased excretion of progesterone in the urine.

Clinically, progesterone both cured and prevented migrainous attacks, whereas stilbœstrol precipitated an attack identical with the naturally occurring one. The excretion of A.P.L. also rises during pregnancy, and A.P.L., by stimulating the development of corpora lutea, is largely responsible for the increased production of progesterone. Individual susceptibility or intolerance to œstradiol was probably an important factor in the causation of migraine in these cases.

Experimentally, headache which may simulate a migrainous attack, severe nausea and vomiting, aches and pains all over the body, especially in the calf muscles, and intense pallor occur singly or in combination in a few persons who are susceptible to stilbœstrol therapy. Milder symptoms are lassitude and languor, loss of appetite, lack of concentration, and vague headaches. Such mild symptoms were complained of by nearly all our migraine patients. Response to treatment with progesterone was complete.

An interesting feature in case 4 was the disappearance of indigestion and pains in the legs, along with migraine, after the fourth month of pregnancy and for six months after parturition. In an almost identical case, where by test-meal examinations it was found that indigestion resulted from hyperchlorhydria and hypersecretion, a fall in the gastric acidity, accompanied by spontaneous disappearance of gastric symptoms and migraine as pregnancy progressed, was noticed. A similar but smaller fall was noticed with progesterone therapy, which relieved the migraine. This and scanty evidence available from a few other cases suggest that progesterone depresses the gastric secretion, probably via the pituitary-hypothalamic mechanism, though retention of sodium in the body caused by progesterone may have an adjuvant effect. Way (1945) has produced evidence that the gastric acidity and the urinary excretion of A.P.L. in pregnancy in women seem to be inversely proportional. It appears from experiments on dogs by Culmer et al. (1939) that A.P.L. diminishes the secretion of free and total acid, and progesterone does not have this effect. These findings suggest the following explanation of our observation in this case: pregnancy→increased A.P.L. (an therefore hypochlorhydria)→increased progesterone relief of migraine.

The menstrual disturbances present in some case suggested hyperactivity of the œstrogens and als responded to progesterone therapy. In one case patch progressive pigmentation of the skin had developed afte three years of migraine; this also has been checked wit progesterone therapy, and is gradually subsiding.

MODE OF ACTION OF ŒSTROGENS

Headache or migraine may be caused by œstrogens in one or more of the following ways:

(1) *By causing temporary enlargement of the pituitary.*—Œstrogens injected into rats of both sexes cause pituitary enlargement (McEuen et al. 1936, Zondek 1936). In the migraine subjects, however, such gross changes are not evident in X-ray films. It is reasonable to assume that even congestion of the pituitary produced by œstrogens would precipitate headache or migraine in them.

(2) *By their effect on blood-vessels.*—The specific effect of ergotamine tartrate on the headache, by virtue of its vasoconstrictor action, is well known. Dilatation of the blood-vessels in the distribution of the common carotid artery, as shown by flushing of the face, conjunctiva, and nasal mucosa of the affected side, leads to vigorous pulsation of the arteries and increased stimulation of the sensory nerve-endings in their coats, and this is probably the cause of headache in migraine. Early cortical symptoms have been attributed to arterial spasm preceding vasodilatation. According to this hypothesis migraine is caused by arterial spasm followed by arterial dilatation within the distribution of the common carotid artery.

Nothing seems to be known about the effect of œstradiol on cerebral blood-vessels, except that intense congestion and hæmorrhages may occur in the pituitary. The results of Markee's (1940) experiments are, however, interesting.

Using a macaque monkey he transplanted a uterine graft to its eye. In the first half of the menstrual period, under œstrogenic stimulation, this graft showed alternate vasodilatation and vasoconstriction of certain areas. At the time of ovulation the vasodilatation was well marked. Just before menstruation vasoconstriction occurred for a day or so and the graft was blanched. This was followed by vasodilatation and rupture of small arteries. It is not known whether the vascular changes in the graft were local and confined to it, or secondary to similar changes in the blood-vessels of the eye. But, if comparison may be made, the primary vasoconstriction followed by vasodilatation in this case is identical with the conception that migraine is due to arterial spasm followed by arterial dilatation within the distribution of the common carotid artery.

(3) *By retention of sodium and chlorides in the body.*—Thorn et al. (1940) have shown that œstradiol injected into normal dogs causes retention of sodium and chlorides. Retention of sodium and chlorides in the brain tissues would predispose to cerebral œdema of the affected areas, and cerebral œdema would certainly lead to headache. However, this would not explain the beneficial effect of progesterone, since progesterone is also known to caus retention of sodium and chlorides. It is reasonabl to assume, however, that in therapeutic doses, pr gesterone would convert œstradiol into the comparativel impotent œstrone and œstriol, and so be utilised instea of circulating in the blood as free progesterone. Ver large doses of progesterone also cause headache, and i this connexion it may be mentioned that Hamble (1939) reported a case of menstrual headache associate with excretion of abnormally large amounts of sodiun pregnandiol glycuronide, and relieved it with intensiv œstrogenic therapy.

SUMMARY

Of 30 women with migraine which had responded poorly to the usual methods of treatment, 23 showed

PROGESTERONE IN THE TREATMENT OF MIGRAINE

The ætiology of migraine is complex and varied. ndividual susceptibility, often inherited as a mendelian dominant, seems to play an important part, and in any given person more than one factor may precipitate an attack, though there is usually a particular predisposing factor.

In some cases endocrine abnormality may be responsible. It appears that thyrotoxicosis predisposes to migraine, patients with exophthalmic goitre being specially liable; but this may be due to the effect of increased pulse-pressure in thyrotoxicosis in a migrainous subject. The onset of migraine at or shortly after puberty and its disappearance with old age suggest that imbalance of sex hormones may be an ætiological factor. In this connexion it is interesting to note its association with the menstrual cycle (menstrual migraine) and its disappearance with the menopause. Therapeutically, 'Emmenin' (Blakie and Hossack 1932) and anterior pituitary-like hormone (A.P.L.) (Moffat 1937) are said to have given beneficial results.

We record here our results in 23 cases of migraine in women, in whom, clinically and therapeutically, œstrogens were established as causal factors in precipitating attacks of migraine. The patients were all successfully treated with progesterone, which not only terminated but also prevented attacks. Facilities for biochemical examinations were not available.

SYMPTOMS

The patients were women between the ages of 21 and 40, and in all of them migraine was the predominant symptom. Its duration varied from about three years in the younger patients to about fifteen years in the oldest. The relation of migraine to menstruation was as follows:

About mid-cycle	12
Premenstrual	4
About mid-cycle and premenstrual	7

The incidence of associated symptoms was as follows:

Excessive and/or prolonged menstruation	16
Intermenstrual bleeding	5
Loss of appetite, lassitude, poor concentration, improper sleep, and vague headaches	21
Indigestion, unclassified	1
Hyperchlorhydria	1
Falling of hair	2
Pain in calf muscles and burning sensation in soles	1
Patchy pigmentation of thighs	1
Tendency to obesity	1
Pallor	3

They were otherwise all healthy, except for the following physical signs in a few cases:

Anæmia	7
Salpingitis	2
Retroverted uterus	4

These 23 cases in which there was clinical evidence of œstrogen hyperactivity form part of a group of 30 cases of migraine in females, which had responded inadequately to the usual methods of treatment. In 27 other cases such treatment had given satisfactory results.

Œstrogen hyperactivity commonly manifested itself in disturbances of menstruation, such as excessive and/or prolonged periods. When these were not present, sensitiveness to œstrogens was shown by inducing a migrainous attack with œstradiol. In all 23 cases migraine could be induced or increased by oral or parenteral administration of 2–10 mg. of œstradiol ('Clinœstrol'), and was relieved by the administration of 5–15 mg. of progesterone ('Lutocyclin'). Usually the amount of progesterone required to alleviate an induced attack of migraine was inversely proportional to the amount of œstradiol used to induce it. To prevent spontaneous attacks the amount of progesterone required was generally *directly proportional* to the severity of the symptoms of œstrogen hyperactivity.

In no case did we inform the patient of the nature and action of the drugs used, and the relief from migraine was associated with disappearance of symptoms of œstrogen hyperactivity. Accordingly, it is unlikely that the success of treatment was due to suggestion. The effects of the drugs were uniform, œstradiol aggravating the symptoms and progesterone relieving them. Early in our trials we treated 7 control cases by injections of distilled water without any effect on the migraine.

ILLUSTRATIVE CASE-RECORDS

Case 1.—Female, aged 40. Periods began at 13. Married when 19. Last and only pregnancy seventeen years ago. Migraine started two years after this pregnancy. Onset at any day between the 10th and the 16th days of the cycle, usually between the 11th and the 13th, rarely premenstrual between the 24th and the 28th days. Periods somewhat excessive and prolonged. Premonitory symptoms of migraine included irritability and a tendency to weep, mutism, and seclusion in bed, loss of memory for time and place, and inability to continue conversation, followed by dimness of vision, blindness, visual hallucinations of snakes and tigers, tingling sensation in, and paresis of, the left upper limb, swelling of the hand and tongue (which continued during the attack), and vomiting. Analgesics, bromides, phenobarbitone, and ergotamine tartrate had an unsatisfactory effect. Complete relief was obtained with two doses of lutocyclin, 2 mg. on alternate days. Period of freedom after treatment with this dosage lasted eight weeks. Relapse occurred about mid-cycle and was controlled with 5 mg. of lutocyclin. Attacks are now mild and less frequent, always occur about mid-cycle, and are easily controlled and prevented by lutocyclin.

Case 2.—Female, aged 29. Periods began at 12. Married when 21. Last and only pregnancy seven years ago. Migraine *started two years after this pregnancy. Onset* any day between the 4th and the 28th days of the cycle. Periods scanty, lasting 2–3 days. Comparative freedom from migraine during this time, though sometimes the most severe attacks developed two days before to three days after the period.

Three months after the onset of migraine scanty intermenstrual bleeding became very frequent, sometimes lasting several days. Continuous ordinary headache or migraine attacks were often associated with intermenstrual bleeding, and their severity was to some extent proportional to the amount of bleeding.

Premonitory symptoms were severe, with giddiness, cold sweating, cloudiness of vision, and diplopia. Analgesics, bromides, phenobarbitone, and ergotamine had little effect except that the last was useful during the actual attack. Complete relief was obtained with four doses of lutocyclin 2 mg. on alternate days. Intermenstrual bleeding stopped. The following period was scanty and lasted two days. The migraine recurred on the 6th day *of menstrual cycle*, but complete relief was obtained with 5 mg. of lutocyclin. Period of freedom then lasted six weeks. Attacks are now mild and less frequent, usually occurring about mid-cycle; they are easily controlled or prevented by lutocyclin in smaller dosage.

Case 3.—Female, aged 29. Periods began at 13. Married when 18. Migraine started at 13 with onset of menstruation. The attacks were severe and associated with excessive menstruation. They were usually mid- and pre-menstrual but at times bore no relation to the period. There was progressive falling of hair.

She aborted three times in early pregnancy during the first six years of married life. The fourth pregnancy, five years ago, appears to have been maintained by administration of crude whole-placenta extracts by mouth. Three months after the onset of this pregnancy migraine disappeared, to return six months after parturition. Now, however, the attacks were mild and irregular; the periods were less excessive, and the loss of hair within normal limits. In the fifth pregnancy, twenty months ago, migraine ceased after three months and did not recur till five months after parturition. The attacks were mild and irregular, often premenstrual, and associated with excessive periods and

All these 10 related persons died suddenly. The following are alive or did not die suddenly:

Two brothers of 1, aged 24 and 36, are alive and well.

One half-sister of 2, aged 43, is healthy and has healthy children.

One sister of 2, aged 34, is alive and has four healthy children.

Three sisters of 5 died from diseases other than apoplexy.

One brother of 5 went to America with seven children; no details known.

The mother of 5, 6, and 7 died in old age from apoplexy, and three of her sisters (aged 60–80 years) died from the same condition; one of these sisters had a "stroke" when aged 20, was ill for a year, but recovered and died aged 59.

Two children of 7, aged about 40, are alive and healthy.

COMMENT

Cerebral angioma is not uncommon, but many of the cases do not come to autopsy or give rise to symptoms. Some of them are cerebellar and some in the region of the third ventricle. Few are in the cerebral white matter, but we record such a condition occurring in more than one member of an Icelandic family.

These cases and the family history suggest the probability of a familial tendency in the formation of some angiomata. Such angiomata may be multiple and give rise to symptoms over a period of years.

Our special thanks are due to Dr. Arni Pjetursson, and one of us (J. N. C.) is indebted to the National Hospital Research Fund for an expenses grant.

PENICILLIN IN POSTOPERATIVE PROGRESSIVE BACTERIAL SYNERGISTIC GANGRENE

REPORT OF A CASE

S. HENRY C. CLARKE
F.R.C.S.
CHIEF ASSISTANT, ST. BARTHOLOMEW'S HOSPITAL, LONDON

PROGRESSIVE bacterial synergistic gangrene is a rare complication of an operation wound, and its prompt recognition is important, because efficient treatment can prevent much loss of skin and a fatal issue.

Cullen (1924) and Christopher (1924) first drew attention to this condition, though Luckett (1909) described a large phagedænic ulcer of the abdominal wall which was almost certainly this same condition. Earlier cases were probably included under the term of hospital gangrene.

Recently cases treated with penicillin have been reported, and this further case may be of interest.

CASE-RECORD

A printer, aged 49, was admitted to the surgical unit, St. Bartholomew's Hospital, on March 14, 1946, with a perforated duodenal ulcer. He was a lean but healthy looking man. He had 10 years' history of intermittent dyspepsia and hunger pains but had never had any medical treatment.

Exploratory laparotomy was performed, six hours after perforation, through an upper right transverse incision, and a small perforation on the anterior surface of the first part of the duodenum was sutured. A drain was inserted into the pelvis through a suprapubic incision, and the laparotomy incision was closed in layers without drainage or antiseptics.

Postoperatively, the patient had some fever from the first day; but, after the drainage of an incisional abscess on the 7th day, the temperature remained normal, apart from a slight rise on three independent days. The incision continued to discharge thick pus, and some sloughs separated.

On the 13th day two extremely tender, raised, red, and indurated areas appeared above and below the inner end of the incision. At first about 1 in. in diameter, in the next forty-eight hours they enlarged to about $1^1/_2$ in. in diameter, and the centres became yellow like a carbuncle.

On the 17th day two patches of gangrene appeared in the centre of the lesion on either side of the incision. These were surrounded by a raised red edge and beyond this by a zone of brilliant red hyperæmia, which spread into healthy skin. The gangrene slowly spread away from the incision, being preceded by a raised red edge and zone of hyperæmia, till there were two patches of gangrene 1–$1^1/_2$ in. in diameter.

A course of 1,000,000 units of sodium penicillin (20,000 units I.M. 3-hourly) was started on the 18th evening. Locally, penicillin cream and dry dressings were applied alternately.

From a swab taken on the 19th day Dr. A. E. Francis reported: "Gram film showed gram-positive cocci, mainly small ones in short chains and a few larger ones in pairs. Culture showed almost pure growth of a micro-aerophilic streptococcus, with a few colonies of staphylococcus."

On the 21st day the condition had stopped spreading, and on the 24th day the sloughs had separated, leaving a clean granulating surface which healed rapidly.

The patient was discharged from hospital on the 35th day, and was seen as an outpatient three weeks later, when the incision was soundly healed.

ÆTIOLOGY

This gangrene may develop in the abdominal skin after the drainage of foul intraperitoneal abscesses, often appendical in origin; gangrenous appendicitis; perforated duodenal ulcers; or other conditions in which the incision has been contaminated with intestinal organisms. It may also develop after the drainage of lung abscesses or fœtid empyemata in the skin of the chest wall. Most of the reported cases have arisen in the region of tight sutures, which are undoubtedly a predisposing cause. In one case, in which the process started some distance away from the incision, a towel clip was thought to be the cause (Lichtenstein 1941).

The condition is a slow but relentlessly spreading gangrene of the skin due to a micro-aerophilic non-hæmolytic streptococcus from the intestinal or the respiratory tract. According to Brewer and Meleney (1926), symbiosis with a non-specific hæmolytic staphylococcus, from either the skin or the air, is necessary for gangrene to develop. Meleney (1931) found, from experiments on dogs, that injections of a suspension of either organism alone, or of both organisms separately in close proximity to each other, did not produce gangrene; whereas, if a 50%-mixture was used, gangrene followed which was similar to that seen in man. Willard (1936), using guineapigs, confirmed these observations. Meleney (1931) points out that the staphylococci are often in small numbers and are easily overgrown on culture by other contaminants, such as *B. proteus*. In some reported cases (Grimshaw and Stent 1945, Mester 1940) a staphylococcus could not be found and therefore some doubt exists about the necessity of a symbiosis. All authors, however, are agreed that a micro-aerophilic non-hæmolytic streptococcus is the essential causal organism of the gangrene.

PATHOLOGY

The micro-aerophilic streptococcus can be grown in pure culture from the subcutaneous fat deep to the spreading edge of hyperæmia or even healthy skin beyond this. Whereas both organisms or other contaminants can be grown from the necrobiotic edge of the gangrene (Meleney 1931), the micro-aerophilic streptococcus only grows anaerobically, except when the swab is taken from the gangrenous area or after subculture, when it may grow aerobically. The staphylococcus concerned is aerobic.

Meleney (1931) could not find any evidence of vascular thrombosis, and considered that the gangrene was due to the specific action of a toxin elaborated by the symbiosis.

CLINICAL FEATURES

The gangrene starts in the 2nd or 3rd postoperative week, but cases have been reported as late as the 4th week (Vier 1940, Dodd et al. 1941), and in one case (Grimshaw and Stent 1945) as late as the 7th week, through drainage of a residual abscess had been performed twenty days before the onset.

The gangrene starts on one or both sides of the incision, often near a tension suture, as an extremely tender red "carbuncle-like" area. The centre of this soon becomes signs of excessive œstrogen activity. In all of these it was shown that œstrogens would precipitate an attack. In all 23 cases progesterone was effective in relieving or preventing attacks of migraine. Various associated symptoms also disappeared with its use.

The name "œstrogenic migraine" might be appropriate for this condition. These symptoms also responded to progesterone. This clinical variety of migraine may be termed œstrogenic migraine.

In a case with a tendency to obesity progesterone had no effect on the obesity, though the migraine was successfully treated.

CLINICAL PATHOLOGIST,
NATIONAL HOSPITAL, QUEEN
SQUARE, LONDON

Elkington[1] in 1935 described some cases with symptoms suggesting that an angiomatous condition in the brain was their pathological basis, and this was confirmed in one case by autopsy and histological findings.

We have clinical, autopsy, and histological records of a patient from Iceland who showed such an angioma in the cerebral white matter, and clinical and autopsy records in a cousin, together with a remarkable family history in which sudden death in young persons is a prominent feature.

The clinical details of the two patients seen by one of us (H. A. K.) are as follows:

Case 1.—A man, aged 22, was admitted to hospital on April 13, 1938, in coma. There had been one previous attack of unconsciousness eight months previously. On admission there was twitching of the face, arm, and leg on the right side, with spasticity of the limbs, more pronounced on the left side. The pupils were equal and reacted to light. No other significant clinical findings were present, and the blood-pressure was normal. Lumbar puncture yielded a bloodstained fluid under an initial pressure of 125 mm. The cerebrospinal fluid (C.S.F.) showed 43 lymphocytes per c.mm., 0·5 g. of protein per 100 c.cm., a positive Pandy, and a negative Wassermann.

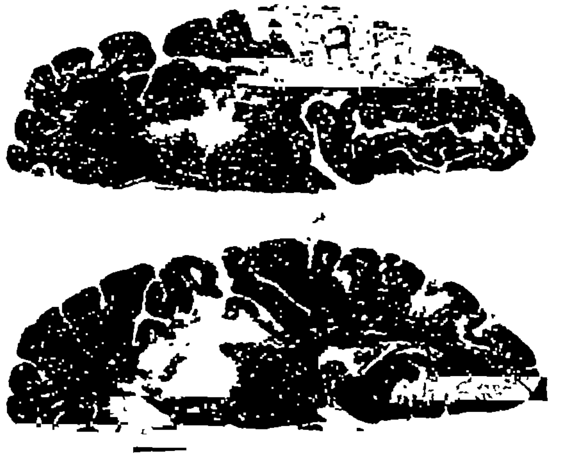

Fig. 1—Left cerebrum showing hæmorrhage in angioma (case 2).

Two days later the patient was confused and aphasic, but able to move the limbs, and had extensor plantar responses.

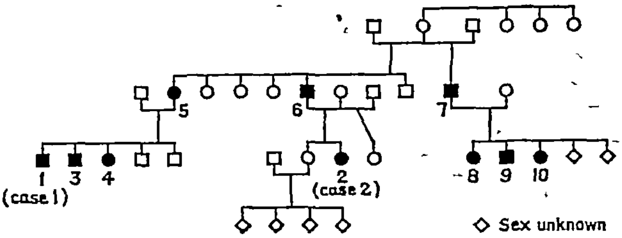

Fig. 2—Pedigree showing relations of cases 1 and 2: solid symbols indicate cerebrovascular accidents in youth; open symbols indicate absence of cerebrovascular accidents in youth.

There was papillœdema of the right disk. The C.S.F. was still bloodstained, with an initial pressure of 165 mm. After six days the left pupil was dilated and the right contracted, but other signs were similar to those seen previously. Stupor increased, and he died twelve days after admission to hospital.

Autopsy.—There was a cyst containing yellow fluid in the left temporal lobe and a large recent hæmorrhage in the right temporoparietal lobe. No aneurysm or vascular disorder was seen. The hæmorrhage was so extensive that it was impossible to demonstrate any angioma.

Case 2.—A woman, aged 33, cousin of case 1, was first admitted to hospital on Jan. 15, 1940, with a history of numbness on the left side for three weeks. There was slight loss of power of the left arm and leg, with exaggerated reflexes on that side, and flexor plantar responses. A slight nystagmus to the left was present. No other abnormal physical signs were found, and blood-pressure, blood-count, and C.S.F. were normal. There had been a similar but milder attack eighteen months previously.

She was discharged with a provisional diagnosis of intracerebral hæmorrhage, and was to return for ventriculography if symptoms persisted. She was readmitted on Nov. 5, 1942, with a week's history of aphasia and weakness of the extremities. A left hemiparesis and some degree of aphasia were present. Coma ensued, and she died four days later, but further clinical notes are not available.

Autopsy.—Abnormal features were limited to the head; the cardiovascular system was normal. The brain was fixed whole and on section showed a hæmorrhage in the white matter of the left hemisphere. This was situated to the lateral aspect of the lateral ventricle, externally and posteriorly to the basal ganglia, extending almost to the posterior tip of the posterior horn, and almost to the cortical grey matter (fig. 1).

Sections cut in celloidin showed a large hæmorrhage with very dilated vascular channels, some of which showed well-marked elastica. The surrounding brain tissue showed much iron pigment, some cuffing of the vessels by lymphocytes, and a few small vessels plugged by thrombus. Some of the many peripheral capillaries were irregular in shape and arrangement, and the appearances were those of an angiomatous condition in which hæmorrhage had taken place.

FAMILY HISTORY

Dr. Arni Pjetursson, of Reykjavik, has kindly supplied the following remarkable details of the family history (fig. 2):

1. Pjetur (case 1) ..	died aged	22.
2. Inga (case 2) ..	" "	35.
3. Jakob	" "	23, brother of 1.
4. Gudrun	" "	23, sister of 1.
5. Kristjana ..	" "	36, mother of 1.
6. Ingimar	" "	30, father of 2, brother of 5, drowned in a swimming-pool although a good swimmer.
7. Hans	" "	42, half-brother of 5 and 6.
8. Elinborg	" "	25, daughter of 7.
9. —	" "	27, brother of 8.
10. —	" "	29, sister of 8.

---

PROGNOSIS

Many of the cases reported in the literature have been diagnosed late, and these have often proved fatal. With early effective radical surgery most patients have recovered, often with considerable loss of skin and scarring. Dodd et al. (1941), reviewing the literature, place the mortality at 20%. It is hoped that with early diagnosis and effective treatment, especially with penicillin, the mortality and the resultant scarring may be very considerably reduced.

SUMMARY

A case of postoperative progressive bacterial synergistic gangrene of the abdominal wall is described.

It promptly responded to intramuscular and local penicillin without the need for radical surgery.

The ætiology, clinical appearances, diagnosis, and treatment are briefly discussed.

I am indebted to Prof. J. Paterson Ross for permission to publish this case and for the help and encouragement he has given me. I also wish to thank Mr. A. M. Boyd, assistant director of the surgical unit, and Dr. A. E. Francis, of the bacteriological department, St. Bartholomew's Hospital, for the bacteriological report.

ESTIMATION OF VITAMIN C IN LEUCOCYTES BY THE HYDRAZINE METHOD

PARIS CONSTANTINIDES *
M.D. Vienna
From the Department of Clinical Chemistry, University of Aberdeen

THE current colorimetric methods of estimating the vitamin-C content of leucocytes are so laborious that only research laboratories can use them.

The commonly employed indophenol method [1] depends on the simple decolorisation of a dye by ascorbic acid; but the lability of both the ascorbic acid and the dye, and the interference of —SH groups such as glutathione, have necessitated the introduction of various safety measures that complicate the technique.

Roe and Kuether [2] developed a new colorimetric method that depends on an entirely different principle—i.e., the production of colour by oxidised ascorbic acid instead of subtraction of colour by reduced ascorbic acid. This method, while extremely sensitive and specific, since the sulphhydryl groups do not interfere, has the advantage that the reagents and the colour produced are stable. There is therefore no need to recalibrate the colorimeter or to restandardise the dye every time; nor has the reading to be taken within 30 sec., as in the indophenol method.

It was therefore thought that the adaptation of Roe and Kuether's method to the estimation of vitamin C in leucocytes might provide an easier procedure, suitable for routine use. Moreover it seemed interesting to compare the values obtained by this method with the values given by the dye methods, as the true vitamin-C content of leucocytes has not yet been definitely established.

METHOD

Reagents.—The following modifications of the original method of Roe and Kuether were adopted:

(1) A 1% solution of 2-4 dinitrophenylhydrazine was used instead of the 2% solution recommended by Roe and Kuether. This was done to increase the difference between the extinction coefficients of the blank and the unknown, and so increase the sensitivity of the method. (There seems to be no stoicheiometric contra-indication to the use of an even more dilute hydrazine reagent—e.g., 0·25%.)

(2) A 2·5% solution of alcoholic thiourea was used instead of a 10% solution.

(3) Ordinary animal charcoal (B.D.H.) was used instead of the unobtainable 'Norit.' It was found active enough, without even having been reactivated, to oxidise more than 99·9% of pure 0·05% ascorbic-acid solutions in 5 min.

The stock of animal charcoal used did not contain any chromogenic substances, and therefore acid washing was omitted.

Carbo activatus (B.D.H.), on the other hand, was unsuitable, as it caused a precipitation after the addition of 85% H_2SO_4, and therefore it appears necessary to check each batch of charcoal on these points before use.

Absorptiometry.—The readings were taken in a Hilger spectrophotometer at 5200 Å, as the red colour obtained under our conditions absorbed at this wave-length more than at 5400 Å, as stated by Roe and Kuether.

The colour has extraordinary stability. No change in the extinction coefficient was noted in four hours with the tubes exposed to daylight, air, and room temperature. Only a slight fall of about 0·01 was noted after four days in the dark.

The blank remained remarkably constant during a whole month of daily estimations.

A calibration curve prepared by plotting concentrations of serial dilutions of a pure ascorbic-acid solution against their extinction coefficients gave a perfectly straight line of direct proportionality in both the spectrophotometer and the photo-electric absorptiometer.

A recalibration of the apparatus with the same reagents after three weeks gave an identical curve. It can therefore be assumed that the reagents last at least that long.

Collection of Sample.—The technique for obtaining the leucocyte-platelet layer was in principle that described by Butler and Cushman,[1] with the following slight differences:

(1) 15 ml. of venous blood is mixed with 0·15 ml. of 20% potassium oxalate, as recommended in an unpublished paper by Lloyd, of Oxford, *instead of the mixture of dry potassium* and ammonium oxalate (Heller and Paul) used by Butler a Cushman. Heparin was unsatisfactory. Icteric blood sampl gave very bad separation with any anticoagulant.

(2) The white and red hæmatocrits are estimated by spi ning Wintrobe tubes for 40 min. at 2700 r.p.m. in duplicate According to the average red hæmatocrit value, 9–11 ml. blood is spun in the special centrifuge tube with a constricte segment near the middle, as described by Butler and Cushma for 60 min. at 3200 r.p.m.

(3) After the plasma has been removed, 15–25 mg. of whi layer is transferred with a glass capillary attached to a syrin into a weighed 15 ml. conical centrifuge tube, which reweighed to obtain the wet-weight of the white mass.

The rest of the procedure is essentially an adaptatio of Roe and Kuether's method to the estimation o vitamin C in the white layer:

After weighing the tube containing the white mass, ad 1 ml. of 6% trichloracetic acid and grind the leucocytes i the acid with the rounded end of a closely fitting glass rod fo 5 min.

Rinse the rod with 1 ml. of 6% trichloracetic acid. Stand it for 5 min. and occasionally tap the tube. Spin the tube for 1 min. at low speed to pack the precipitate at the bottom. Add a pinch of charcoal (about 0·05 g.) to the supernatant fluid. Stand the tube for 5 min. and tap it occasionally.

Filter through Whatmann no. 42 or 44 (5·5 cm.) paper into a clean test-tube. Transfer 1 ml. of the filtrate into purple and then gangrenous. The lesion now consists of three zones: a centre of brownish-black gangrene, like suede leather, surrounded by a raised purple or red edge, and beyond this a zone of brilliant red hyperæmia fading off into healthy skin. The hyperæmia slowly spreads in all directions away from the incision and is succeeded by the raised edge and then by gangrene; hence the lesion slowly creeps over a large surface of the body during the course of nine months to a year (Stewart-Wallace 1935). The gangrene is superficial; and, as the condition spreads, the oldest part nearest the incision may liquefy, leaving a red granulating area. This may epithelise in patches from surviving epithelium in the deeper parts of sweat glands and sebaceous glands. At the spreading edge of the ulcer, however, there are always three zones of hyperæmia, raised edge, and gangrene.

2. Roe, J. H., Kuether, C. A. *J. biol Chem.* 1943, 147, 399.

There is usually little if any general reaction; but extreme depression, leading sometimes to serious mental change, is common as a result of the severe pain, especially on dressing the wound, and the relentless progress of the disease.

DIAGNOSIS

Diagnosis is made on the clinical appearance of the three zones, the history of an operation, and the finding of the specific organism. For bacteriology a small biopsy specimen of the growing edge of the ulcer may be required.

Meleney (1933) classifies gangrene of the skin into acute and chronic. Three main types of acute gangrene have to be differentiated: gas gangrene, hæmolytic streptococcal gangrene, and erysipelas.

Gas gangrene mainly involves muscles, and general toxæmia is pronounced; but, near the wound, limited redness and œdema may, after becoming dusky, progress to a very limited gangrene of the skin.

Hæmolytic streptococcal gangrene is a spreading necrosis of the subcutaneous fat, with thrombosis of the vessels supplying the skin, leading to a secondary gangrene of the skin. Phagedæna and Fournier's gangrene are probably examples of it. It follows a superficial wound. Swelling and redness spread quicker than in erysipelas, and the edge is not raised. On the third, fourth, or fifth day a dusky purplish patch with an irregular margin appears in the centre but not necessarily in association with the wound. Blisters soon form, and other patches may appear, which may coalesce into a large gangrenous sheet unless longitudinal tension-relieving incisions are made through the area into healthy tissue on either side. Hæmolytic streptococci can be recovered from the centre of the lesion, but often not from the hyperæmic outer zone, as opposed to erysipelas, in which the organisms are mainly found in the spreading edge. Secondary infection may follow.

Erysipelas has a raised edge, and the rate of spread is slower. The centre is often pale, and gangrene is rare.

In the chronic group postoperative progressive bacterial synergistic gangrene, chronic undermining ulcer (Meleney 1935), gangrenous impetigo, fusospirochætal infection of the skin, and amœbiasis cutis have to be considered.

Chronic undermining ulcer is characterised by the absence of gangrene, much undermining of the skin, and the presence of only an anaerobic streptococcus on culture.

Gangrenous impetigo, also called ecthyma, pyoderma gangrenosum, and dermatitis gangrenosa, consists of multiple lesions which start as small vesicles surrounded by a red zone, the centre of which becomes gangrenous and depressed. This separates from healthy tissue, leaving a ring of ulceration with a gangrenous scab in the centre. When the scab separates a thin scar is left. The condition is contagious and occurs mostly in debilitated persons. It is considered to be a severe form of impetigo.

Fusospirochætal infection follows human bites or contamination of wounds with mouth organisms. Streptococci, fusiform bacilli, and spirochætes, either all three or two of them, are found; anaerobic culture is usually required. Cancrum oris and noma are often examples of this, and probably many cases of hospital gangrene were also. The w[illegible] foul discharge, and its edges become shaggy and grey-green and bleed easily. The infection rapidly spreads into bones and joints and often along the deeper tissues, to come to the surface at some distant site and so cause multiple sinuses.

Amœbiasis cutis may follow contamination of a wound after the drainage of amœbic liver abscesses or after operations on the colon. After some days or weeks the drainage tract becomes red and indurated, the edges become everted and raised, and the surrounding skin dark brown with hyperpigmentation. As the necrosis spreads, "raw-beef-like" granulations are left, in which no regenerating epithelium is found as in postoperative spreading gangrene, and the gangrene may involve muscles besides skin. Amœbæ may be found in the glairy pus expressed from the margin, and the response to intravenous emetine is usually rapid.

TREATMENT

Prophylactically, tight sutures should be avoided after the drainage of foul intraperitoneal abscesses or fœtid empyemata (Meleney 1931). Whether sulphonamide or penicillin powder locally would prevent this complication is not known. Mester (1940) thought sulphonamides had helped, but Meleney et al. (1945) found that sulphadiazine given by mouth did not prevent gangrene in their cases. They also found that penicillin injected locally for the established condition did not improve it.

Before the introduction of penicillin the only treatment was a radical excision of the affected area well beyond the spreading zone of hyperæmia, or, if that were not possible, an encircling incision. The wound was then smeared with "active" zinc-peroxide paste. Neary and Rankine (1943) describe a method of testing "activity." Later, in 10–14 days, the raw area is skin-grafted. Many of the reported cases which recovered were treated without peroxide, which is probably unnecessary provided the excision is radical enough and through healthy skin well beyond the hyperæmia. Meleney (1933) prefers the scalpel, because it produces less sloughing than the cautery. In no circumstances should the wound edges be drawn together with strapping (Vier 1940) or sutures (Nightingale and Bowden 1934), as this favours recurrence.

Antiseptics, hypertonic dressings, radiant heat and various lights, zinc peroxide and oxidising agents alone, and X rays have all been tried on several occasions; but, apart from an isolated case in which recovery may have been spontaneous, they have been completely ineffective (Dodd et al. 1941).

There are few reports of treatment with penicillin. Grimshaw and Stent (1945) report a case, following a perforated duodenal ulcer, treated with 500,000 units I.M. over five days, which responded within forty-eight hours, the patient recovering without radical surgery. Meleney et al. (1945) also report three cases, two of which, a lung abscess complicated by empyema, and a strangulated internal hernia requiring resection and ileostomy, were cured with penicillin, the total dose not being stated. Their third case of unusual multiple gangrenous ulcers resembled but was not proved to be this condition; it responded partially to penicillin but required excision before the condition was finally controlled. In the authors' opinion the unusual factors were due to the presence of penicillin-resistant gram-negative organisms. The patient died of a pulmonary embolus.

In the present case the response to penicillin was dramatic, and radical surgery was not required. The lesion healed so rapidly that even skin-grafting was not necessary.

Further trial of penicillin is needed before its curative effect can be completely accepted, but so far the results have been good. Grimshaw and Stent (1945) state that the organisms in the pus from their case were sensitive to one drop of penicillin solution of a strength of 1 unit per c.cm., but I have been unable to discover whether it is effective against both members of the symbiosis.

advances in the theory and application of knowledge of blood coagulation are well represented. Adequate sections on the Rh factor—Fisher's nomenclature is fully described—and folic acid are included. Treatment with radioactive phosphorus applied to leukæmia and polycythæmia is described in detail, as is the use of nitrogen mustards in leukæmia and Hodgkin's disease. Corrected ideas on the site of the gastric lesion in pernicious anæmia are given. New plates show malarial parasites. We are glad to see that Professor Wintrobe continually condemns the use of "shot-gun therapy" in anæmia and emphasises its expense. He gives a timely warning that photoelectric colorimeters require just as careful standardisation and use as other types: commercial patterns may be up to 20% inaccurate when received.

Diseases of the Retina

HERMAN ELWYN, M.D., senior assistant surgeon, New York Eye and Ear Infirmary. London: J. & A. Churchill. 1947. Pp. 587. 45*s*.

WITHIN the limits he has set himself, Dr. Elwyn has written a useful book, well produced and handy in size. Inspection is the only method open to the doctor who examines the retina, and a book on retinal disease ought to illustrate the ophthalmoscopic appearance of all the more usual fundus disorders; it is a pity, therefore, that the good coloured illustrations are not more numerous. The description of each fundus condition opens with a brief historical review, goes on to the clinical manifestations and course of the disease, and ends with pathology and treatment. Dr. Elwyn's own experience does not come much into the picture, and the descriptions are mainly a review of current thought. While this is helpful, most readers value more exact case-histories quoted by an author from his own recorded observations, and followed to their conclusion. The book being mainly medical, details of the operative surgery of retinal detachment seem out of place in it; but it contains much useful information given clearly and with moderation, and the coloured plates more nearly resemble the diseases they depict than is generally the case in textbooks.

Diseases of the Heart and Circulation

ALBERT A. FITZGERALD PEEL, D.M. Oxfd, F.R.F.P.S., professor of medicine, Anderson College of Medicine, Glasgow. London: Oxford University Press. 1947. Pp. 398. 35*s*.

STUDENTS will find Professor Peel's book a reliable, if at times dull, introduction to cardiology. Based on lecture notes, the book is more academic than practical in approach, dealing first with symptoms and physical signs, then with anatomical lesions, and finally with ætiology. Some will feel that the section on anatomical lesions should have been incorporated in the section on ætiology; for modern cardiology stresses the importance of cause—whether rheumatic, syphilitic, or arteriosclerotic—and the functional state of the myocardium. The student may get the impression, too, that "mitral stenosis" or "aortic incompetence" is itself a diagnosis. Thus a full description is provided of the signs of a fully developed mitral stenosis, but little attention is paid to the development of this lesion and its significance as a guide to the state of the underlying rheumatic pancarditis. A welcome feature of the book is that more attention than usual has been given to treatment.

Retinal Structure and Colour Vision

E. N. WILLMER, SC.D., lecturer in histology in the University of Cambridge. London: Cambridge University Press. 1946. Pp. 231. 21*s*.

COLOUR-VISION is a subject which has always attracted theorists, no doubt because none of the explanations so far produced, not even the famous Young-Helmholtz theory, has been obviously and finally satisfactory. Dr. Willmer's hypothesis (he specifically refuses to call it a theory) is definitely one to be taken seriously but not to be swallowed whole. While accepting the necessity for three retinal mechanisms to cover the facts of human colour-vision, he rejects the classical view that colour-vision is confined to the cones and seeks to explain the phenomena in terms of the known reactions of both rods and cones. In doing so he is forced to postulate two different types of rod, both containing visual purp but one capable of dark-adaptation and the other (the "day rod"). There seems to be little more eviden in favour of the "day rod" than there is in favour the three different types of cone required by the Yo Helmholtz theory, though it is only fair to remember that Granit, in a purely experimental approach to retinal physiology, has found it necessary to assume that some rods are incapable of dark-adaptation. Unfortunately Dr. Willmer accepts rather uncritically some of the evidence in favour of his hypothesis, while evidence tending in the other direction is often either ignored or rejected on insufficient grounds; in the main, however, this applies only to minor points. He also has a disconcerting way of making startling and unusual statements without giving adequate references for them. The book is certain to arouse opposition, especially among those who have accepted the classical explanations of colour-vision and who do not want to have their ideas upset. The best possible antidote to this attitude is provided by W. D. Wright's foreword, which should be read and taken to heart by anyone who wishes to tackle an interesting and provocative book.

Practical Malariology

PAUL F. RUSSELL, M.D., M.P.H., colonel, M.C., A.U.S., parasitology division, Army Medical School; LUTHER S. WEST, PH.D., head of biology dept., Northern Michigan College of Education; REGINALD D. MANWELL, SC.D., professor of zoology, Syracuse University, New York. London: W. B. Saunders. 1946. Pp. 684. 40*s*.

WRITTEN by authors whose practical experience and acknowledged reputations are hallmarks of their competence, this manual gives a comprehensive account of malaria and its control. Though written in the closing months of the war, and embodying much military experience of malaria, it discusses control primarily from the standpoint of civilian needs.

In the chapters on life-cycle, morphology, and physiology, all technical methods for demonstrating and studying the parasites are set out. The mosquito is exhaustively described in terms of morphology, taxonomy, life-cycle, bionomics, and distribution; and the authors describe ably the technical procedures for collection of specimens, for their identification and study, for making mosquito surveys, for testing anti-mosquito agents, and for experimental work in the entomological laboratory. An important section on the community problems of malaria discusses epidemiology, climatology, and the science of malaria surveys. A large appendix gives keys to world anophelines. Beautifully illustrated with drawings, photographs, and coloured plates, the book is a polished piece of work.

Erkennung und Behandlung der organischen Lösungsmittelvergiftungen (Berne: Hüber. 1947. Pp. 168. Sw. fr. 13·80).—The toxicology of the volatile industrial solvents is yearly becoming more commonplace, but published work on the subject is widely scattered, largely uncritical, and tedious to study and evaluate. This slim comprehensive monograph by Dr. Franz Borbely sets out under general and special sections the sources, commercial and domestic forms, and clinical symptomatology of these poisons. The analytical and special laboratory aspects of the subject are not so extensively dealt with, for this is essentially a handbook for the industrial medical officer. It is well documented with references to published cases.

Anatomical Terms: Their Origin and Derivation (Cambridge: Heffer. 1947. Pp. 165. 7*s*. 6*d*.).—Compiled for the increasingly large proportion of medical students who have not had a classical education and therefore do not know and cannot guess the meanings of words derived from Greek or Latin and met for the first time, this book, by Dr. E. J. Field and Dr. R. J. Harrison, can easily be carried in the pocket for rapid consultation. A knowledge of the derivation of a word helps one both to remember its meaning and to spell it properly. Besides derivations this dictionary includes short biographical accounts under eponyms (even to the dipping of Achilles). Now we want a companion volume for medical terms, such as "poikylocytosis," "poliomyelitis," "anaphylaxis," and "dysdiadochokinesia."

nother test-tube. Add a small drop of 2·5% alcoholic thiourea olution and 0·25 ml. of 1% hydrazine reagent. Stand it or three hours in a water-bath at 37°C; then dip it into a eaker containing ice-water. Add 1·25 ml. of 85% H_2SO_4, drop by drop, cautiously from a pipette. Mix by shaking under he ice-water. Remove it to a rack and let it stand for 30 min.

A blank is performed on 2 ml. 6% trichloracetic acid n exactly the same way—i.e., add a pinch of charcoal, c. It need only be run during the first estimations, until ne is satisfied with its constancy. It is advisable to run blank once in two weeks to check the reagents.

The extinction coefficient E_X of the unknown solution nd E_{BL} of the blank are read on a spectrophotometer r a photo-electric absorptiometer.

Calculation.—A calibration curve for the instrument s prepared from vitamin-C solutions in 6% trichloracetic cid ranging from 2 γ/ml. to 20 γ/ml. and a blank. A pinch of charcoal is added to 2 ml. of each solution, and he procedure described above is carried out. The xtinction coefficient of each solution is determined, nd E_X–E_{BL} is plotted against the vitamin-C concentration n γ/ml.

The concentration of vitamin C of the test solution in γ/ml. is read off from the calibration curve, and the result expressed as mg. of vitamin C per 100 g. of leucocyte-platelet layer by the formula $\frac{200\ C}{W}$, where C=concentration of vitamin C in γ/ml., and W=weight of the white-layer sample in mg.

Time.—The "active time" of the method is 50 min., even with several simultaneous estimations. But, as the inactive time (centrifugations, incubation, &c.) comprises five hours, it is advisable to start in the forenoon.

EFFECT OF SPINNING CONDITIONS

The weight of every white-layer sample, however intensively spun, is never identical with the true weight of the leucocytes and platelets. It always includes the weight of some plasma and red cells. Various degrees of white-layer density and purity give therefore different vitamin-C values for the same apparent weight. This was demonstrated by estimating the vitamin-C values in the white layer of two healthy persons at three different centrifuge speeds. The results were as follows:

Ascorbic acid (mg. per 100 g. white layer)

	15 min. at 2400 r.p.m.	*40 min. at 2700 r.p.m.*	*60 min. at 3200 r.p.m.*
Case 1 ..	15·5	29	36·9
Case 2 ..	17	25	38·7

It is obvious that, in any survey, the vitamin-C values will vary with the spinning conditions, and it was found in practice that centrifuging at 3200 r.p.m. for 60 min. gave maximal values. With this speed and time the white layer is densely packed and its average histological purity greater than 95%.

In every case smears stained with Leishman confirmed that the "white layer" displays a typical heterogeneous structure. The top of the column is always occupied by a pure mass of thrombocytes and small lymphocytes. The middle and lower parts contain the large lymphocytes and the granulocytes, with a variable infiltration of red cells at the bottom.

RESULTS

An examination of seven healthy persons aged 20–36 gave values ranging from 20 to 39 mg. per 100 g., with a plasma range of 0·4–1·4 mg. per 100 c.cm.; the average white-layer level was 29 mg. per 100 g. Duplicates performed on plasma showed a maximal difference of ±1%. Duplicates performed on white layer showed a maximal difference of ±12%. The greater discrepancy in the case of the white layer is probably due to the heterogeneous cytological composition. (The normal white-layer range found by Butler and Cushman[1] was 25–38 mg. per 100 g., their average normal value being 34 mg. per 100 g.)

In a case of acute clinical scurvy, on admission, ascorbic acid was absent from the plasma, but the white-layer level was 9 mg. per 100 g.

DISCUSSION

The ascorbic-acid content of leucocytes estimated by the hydrazine method agrees with the values given by the indophenol method. It therefore seems probable that the values which Butler and Cushman[1] obtained by the indophenol method and called "apparent" values do represent the true values, though the ultimate test would consist in simultaneous examinations of each specimen by the two different methods.

Our lower average value cannot be considered conclusive, as it is not yet statistically supported. It may, however, reflect the difference in nutritional level between the post-war British and the pre-war American populations.

SUMMARY

The hydrazine method of Roe and Kuether has been modified and adapted to a micro procedure for the estimation of vitamin C in leucocytes and platelets.

Estimations were made by this method in seven healthy persons and in one case of acute clinical scurvy. The values found in the healthy persons were 20–39 mg. per 100 g. and thus agree with the range obtained by the indophenol method.

Different spinning conditions and anticoagulants affect the histological composition of the white layer and interfere with the correct estimation of its vitamin-C content.

My thanks are due to Dr. A. Lyall for permitting and encouraging this investigation in his department.

Reviews of Books

A Synopsis of Orthopædic Surgery

DAVID LE VAY, M.S. Lond., F.R.C.S., orthopædic surgeon, Woolwich Memorial Hospital. *London*: H. K. Lewis. 1947. Pp. 242. *15s.*

Mr. Le Vay acknowledges his free use of Brailsford's, Girdlestone's, and Jones and Lovett's larger and well-authorised orthopædic works, and this may partly account for the success of this little book; but he is to be congratulated on the way he has pruned those larger works, and still written a textbook which will stand on its own feet. The text is lucid and never becomes a mere catalogue of names; written for undergraduates, it is factual, but though controversial matters are not discussed the facts are there in abundance, and the book would be useful—perhaps even more useful—to postgraduate students. References would be welcome in a second edition.

Clinical Hematology

(2nd ed.) M. M. WINTROBE, professor of medicine, University of Utah, Salt Lake City, U.S.A. London: H. Kimpton. 1946. Pp. 862. *55s.*

THE advances of the four years that have elapsed since the first edition of this book are fully covered, and revision of detail has been thorough. A welcome new chapter brings together much information on the "metabolism" of erythrocytes; this deals with the biochemical aspects of the production and destruction of red blood-cells, hæmoglobin metabolism, the place of the porphyrins, new evidence on iron metabolism derived from studies with radioactive tracers, the importance of the various vitamin-B-complex members, pigments, and an informative section on the fate of worn-out red cells. Much of this information is not yet really digested, and it is not the author's fault if parts of the chapter are a somewhat confusing catalogue of apparently unrelated detail—for example, "xanthopterin is a yellow pigment isolated from butterfly wings which has been shown to have hemopoietic activity in Chinook salmon." Recent

Varicose veins

the most **efficient**
injection treatment

'Ethamolin' offers specific advantages over any other sclerosing agent for varicose veins Given sufficiently early, 'Ethamolin' frequently brings *lasting* benefit; marked relief can be obtained even in cases of prolonged untreated varicosity. 'Ethamolin' forms a firm, adherent thrombus Sloughing is not caused if the solution escapes around the vein and there are no general reactions except in the very rare case of hypersensitivity. The total dosage required is normally less than 6 cc, being powerfully bactericidal, 'Ethamolin' reduces the risk of infection to a minimum.

With 'Ethamolin' the practitioner is thus equipped to deal with the majority of his varicose patients without need to resort to operative measures

2 cc Ampoules: Boxes of 6 and 100.
Bottles of 15 cc. and 30 cc.

ANETHAINE ANAESTHESIA

rapid...effective...controlled

'Anethaine' (amethocaine hydrochloride) is a local anaesthetic effective in one-tenth the amounts required with procaine. It is active by surface application as well as by injection and dosage can be conveniently controlled to procure the required degree of anaesthesia.

For surface anaesthesia, 'Anethaine' is available in powder, solution (2 per cent.), solution tablet and ointment forms 'Anethaine' has a wide field of application in ophthalmology, oto-rhino-laryngology, urology and proctology. It is also used to relieve pruritus in skin disorders

'Anethaine' Ointment, containing a 1 per cent. amethocaine base, is particularly useful in alleviating the extreme discomfort of haemorrhoids, and as a lubricant to facilitate instrumental examinations

For infiltrative anaesthesia, 'Anethaine' is presented in ampoules containing 100 mg amethocaine hydrochloride as a sterile powder Injected in small doses at concentrations of 1 4,000 to 1 1,000 'Anethaine' achieves maximum muscular relaxation throughout prolonged operations

For spinal anaesthesia, 'Anethaine' spinal Ampoules (freeze-dried) provide a means of producing, in small dosage, anaesthesia lasting 1¼ to 2 hours—adequate for almost any surgical requirement without being unduly prolonged. The incidence of undesirable side-effects is low.

AMETHOCAINE **ANETHAINE** HYDROCHLORIDE

GLAXO LABORATORIES LTD, GREENFORD, MIDDLESEX. BYRon 3434

The survey provided some useful information about the amount of medical attention received. In these adult samples 56% of the people were insured, and 95% of the insured relied on a panel doctor for their medical care. The private patients saw their doctor appreciably more often than the panel patients, the average number of consultations in the winter period being 1·76 for private and 1·31 for panel. In the whole sample the average number of consultations per head worked out at about half of one per month. About 30% of the ill saw their doctor at his surgery and 13% were visited at home: it would be interesting to know whether home visits were more plentiful among insured or among private patients, but this division is not made in the report. Nearly 3% of the ill attended a hospital outpatient department and no less than 8% sought advice from their chemist; 3·5% consulted a dentist, 2% an optician, and 3% a nurse or others.

The publication of a periodical statistical analysis of morbidity in the Registrar-General's quarterly returns will provide a record of the changes in the nation's health resulting from seasonal fluctuations, epidemics, and the effects of variations in policy, habits, and conditions. The surveys will also reveal more stable relationships between health and sex, age, income, and environment. Special inquiries can be made by adding supplementary questions to the schedules or by making a special survey among a selected sample of the population—in January of this year, for example, the incidence of deafness was inquired into for the Medical Research Council. Other plans under consideration are to study the relation between the health of old people and their occupations; and to obtain information about the health of people living under special housing conditions. It is proposed to extend the survey to cover all ages, and to record the health experience of a sample of complete families over a year. With such an organisation in full swing it should be possible to gauge fairly accurately the type and extent of our disorders for which the National Health Service must provide.

Iodine and Goitre

IT is useful from time to time to overhaul our beliefs and make sure that they still hold water. Nevertheless anyone who sets out to "debunk" some established method of preventing disease assumes a certain responsibility, particularly nowadays when the lay press is ever on the lookout for a startling break with tradition. Lately Dr. ISIDOR GREENWALD,[1] of New York, has denied that lack of iodine in food or water is the chief cause of endemic goitre, and his views, which the *Journal of the American Medical Association*[2] calls "extraordinary folly, unsubstantiated by anything resembling scientific evidence," have been widely quoted in the American press. Having almost certainly convinced many readers, both medical and lay, these views might therefore form a basis for serious opposition to the preventive measures now being pressed forward. It will be recalled that the Ministry of Health has recently decided to add iodine to the vitamin preparations distributed to expectant mothers, while the Goitre Subcommittee of the Medical Research Council[3] is urging the gen adoption of iodised salt, and the United States Congress is being asked to make the iodisation of table salt compulsory.[2]

It was CHATIN[4] in France, in 1852, who first established that the iodine content of water, food, and soil was low in regions of endemic goitre, but his work was discredited and then forgotten until BAUMANN[5] in 1896 discovered that iodine was a normal constituent of the thyroid. MARINE was one of the pioneers in demonstrating the relationship of iodine to thyroid structure and in showing that the iodine store varies inversely with the degree of active hyperplasia. In 1935 he said that, as CHATIN's observations had been generally confirmed by all workers, the view that goitre was caused by some specific virus or toxin must be abandoned.[6] It is now accepted that endemic goitre is a compensatory hypertrophy whose essential cause is a relative or absolute insufficiency of iodine, and on this basis large-scale attempts to prevent goitre by adding iodine to table-salt (usually 5–10 mg. of potassium iodide per kg. of salt) have been undertaken in Switzerland, Canada, America, Germany, Poland, Australia, and New Zealand, all with favourable results

GREENWALD argues that if endemic goitre really does arise from lack of iodine: (1) goitrous people should have low basal metabolic rates; (2) goitrous thyroids should contain less iodine than normal glands, not only per gramme of tissue but per entire gland; and (3) one should be able to produce goitre in animals by placing them on iodine-poor diets, and to prevent it by adding to these diets such small quantities of iodine as are found in ordinary foods The first of these assumptions is surely a non-sequitur and does not deserve consideration. Turning to the second, we do not see why, with progressive enlargement, the total iodine content of a goitre should not equal that of a normal-sized gland, though the concentration would be considerably less. As regards the third, goitres have in fact been produced by iodine-poor diets; but it is true that these experimental goitres cannot always be prevented or cured without giving the animal more iodine than a normal diet contains, and it is quite possible that some undiscovered factor is concerned. GREENWALD quotes the work of THOMPSON,[7] who showed that the addition of large amounts of iodine prevented goitre, whereas small amounts did not, and suggests that iodine may check a goitrogenic factor in some diets. Even this, however, does not argue against iodine-lack as a factor in the disease. GREENWALD makes much, too, of what he regards as uncontrolled analyses of natural waters, though actually few workers have attached much importance to the iodine content of water except as an indicator of the available iodine in the soil. (SHORE and ANDREW[8] in New Zealand found that generally speaking the incidence of goitre varied inversely with the iodine content of the soil, though there were unexplained anomalies.) He is also perturbed at the lack of controls in assessing the iodine content of vegetables, pointing out that the iodine

THE LANCET

LONDON: SATURDAY, MAY 31, 1947

Prevalence of Sickness

UNTIL the last few years there was no reliable measure of the amount of non-fatal illness among our population; for only certain infectious diseases are notifiable, while the records of hospitals and national health insurance do not give an overall picture. This gap in our knowledge was particularly embarrassing during the war, and the Report of the Ministry of Health for 1946, just published,[1] describes some of the efforts made to close it. A fundamental step was the preparation of a coded classification of diseases and injuries [2] by a committee of the Medical Research Council in 1943; this is now used in Great Britain, but it is hoped that by next year all countries will have accepted the new international classification, covering causes of death as well as diseases and injuries, which is being drafted for the World Health Organisation. Further information was obtained from the records of admissions to E.M.S. hospitals, and from the sickness records of a number of firms collected by the Industrial Health Research Board. Finally, great success has been achieved by the monthly analyses of the health of random samples of the population instituted in 1944 by Social Survey, with the support of the Ministry of Health. Some of the survey's results have already been published, in the *Monthly Bulletin of the Ministry of Health*, by Dr. PERCY STOCKS, medical statistician to the Registrar-General, who has been principally responsible for devising and guiding the investigations, and future findings are to appear in the Registrar-General's quarterly returns. The first full report [3] traces the course of these studies from their inception up to the end of 1945.

The first survey for what has become known as the "health index" was made in January, 1944, to collect information about the previous three months. Further surveys, each covering the previous three months, were made during six months of 1944; and since February, 1945, a survey has been made every month. The number of schedules collected at each survey ranges from 2000 to 2500; and strict precautions are taken to make these truly random samples of the population between the ages of 16 and 64. From the start the public have given their willing support, fewer than 1% having refused to answer questions; this is perhaps partly because the interviewers are mostly women experienced in social work, though it is human nature to welcome a ready listener to the tale of one's misfortunes. The selection and training of the 300 interviewers employed is the task of six regional organisers, who hold a monthly conference with the research officer responsible for the health index, when flaws in the schedule are sought and corrected Despite all care the results cannot be taken at their face-value. Experience has proved that memory of minor illnesses, good for the immediately preceding month, is not so good for the month before that, and is worse still for the first of the three months under survey. Some people mention complaints which others would think too trivial; some statements are patently wrong (e.g., on the state of the teeth); and some information is intentionally withheld (e.g., about venereal diseases). Reliance on the patient's own diagnosis is probably not a source of serious error, for when in a similar survey in the United States the diagnoses were referred to the patients' doctors for confirmation there was agreement in 90%. One difficulty is the tiresome irregularity of the calendar: January figures cannot be compared with those for February without allowance for the three days' difference. Moreover, minor changes in procedure may produce apparent alterations in the incidence of disease, and variation in the quality of the samples (for instance, through demobilisation) may give a false impression of general improvement or deterioration.

The simplest count is of the number of people in each sample who have reported any kind of illness or injury during the preceding three months. The figures for corresponding months in 1944 and 1945 were very similar, the anticipated ebb and flow between summer and winter occurring in each year. For 1945 the percentage ill was highest in March (82%) and lowest in September and October (both 69%). The general increase of illness in the winter is attributed almost entirely to colds and influenza. Other main types of illness arise fairly steadily throughout the year, except "rheumatism" and nervous complaints, which appear to be more common in the summer, possibly because when people have no winter ailment they are more prone to complain of vague aches and pains or their nerves. In one winter period 79% of the sample reported some illness and 3·8% an injury, but only 70% of the injured also had an illness and only 3·3% of the ill also had an injury, which suggests that illness and injury do not go together, though regions with high illness-rates tend also to have high injury-rates. The proportion of the sample reporting illness rose steadily from the age of 16 to 64, but the amount of new illness decreased with advancing age; liability to injury was appreciably greater under than over 30 years of age. The incidences of both illness and accident were appreciably higher in urban than in rural areas, and there were pronounced differences between regions, not ascribable solely to varying degrees of urbanisation. The incidences in different occupations also vary widely; some occupations, such as agriculture and fishing, have low rates of both injury and illness, but on the whole occupations where injuries are common have low rates of illness, and vice versa. Health is related to wealth—liability to illness increases as income falls—but liability to injury is unaffected by income-level. Surprisingly perhaps, no relationship was established between total illnesses and number of persons per room in the household, but people living more than one to a room were particularly liable to some diseases, notably those of the mouth and teeth, and relatively free from others, such as cardiovascular disorders. Women, it was found, reported about 25% more minor ailments than men, but for more serious illness there was little difference between the sexes.

[3] The Social Survey: Survey of Sickness, October, 1943, to December, 1945, by Patrick Slater.

in many of the children classified as P.-I. or W.P.-I. reactors, there was a well-marked rise in titre three weeks afterwards, whereas in the N.-S. group all except 1 had no agglutination titre at the time of the test, and none retested three weeks afterwards showed any rise.

Felton and Flosdorf [20] used the agglutination test in investigating an epidemic of pertussis in a children's home. Of 74 children (including 9 cases of pertussis) skin-tested at the start of the outbreak, 34 were classified as N.-S., 21 as W.P.-I., and 19 as P.-I. The reactions in the 9 children suffering from whooping-cough at the time of the test were equivocal. Eight secondary cases occurred, 6 from the N.-S. group and 2 from the W.P.-I. group (the latter had no demonstrable agglutination titres at the time of the test). The skin-testing once more led to a definite rise in agglutination titres estimated a month later. The elevation might have been ascribed to the presence of pertussis in the home, but in another group of children living under similar conditions except that there was no evidence of pertussis a similar rise was found after skin-testing. In an outbreak investigated at another home, the 5 secondary cases occurred in the N.-S group. Smolens and Mudd [21] extracted agglutinogen by chemical methods instead of sonic disruption of the bacterial bodies, and Felton et al.[15] compared the reactions from the two types of agglutinogen, concluding that 5 units of the acid-extracted substance (designated E.-I) was equal to 10 units of the sonic extract (A.-I). In an institutional epidemic in a children's home, where pertussis was almost a yearly occurrence, the children were tested with both types of agglutinogen in 1943. When an epidemic occurred after skin-testing was completed all 10 cases were in the N.-S. group. Subsequently all entrants have been skin-tested and the susceptible immunised. No further outbreaks have been recorded.

Thus agglutinogen is apparently a stable fraction of the pertussis bacillus, which, when freed from toxic components of the disrupted organisms, gives consistent results in the detection of immunity or susceptibility. It has also a pronounced stimulating effect on the production of agglutinins, and if these early findings are confirmed, it may have an important rôle either as an immunising agent in itself or as a means of increasing the protective antibodies of children already immunised with whole bacterial vaccines.

Proper Care of the Old

Protests about the neglect of old people are common and shocking enough. Yet, bad as things are, some hospitals, some counties, some voluntary bodies, and some individuals are already making a good job of looking after the old. Believing that it may be useful to describe a few of the best examples, we open in this issue a series of articles on Modern Care of Old People, beginning with an account of capable treatment in hospital. Other articles will discuss homes and housing for those who are well, special methods of treatment for the ailing, and ways of overcoming staffing difficulties. None of these homes or hospitals can claim to have achieved perfect care of the old; but in all of them those in charge have grasped that their task is active not passive; they have shaken off inertia, and, whatever the frustrations and handicaps, are set on steady advance. We hope they will infect others with their discontent.

Annotations

BOVINE TUBERCULOSIS IN THE LUNGS

The part played by the bovine tubercle bacillus in the causation of non-pulmonary tuberculosis has been studied by several workers in Great Britain, Scandinavia, Germany, and the United States, and is now fairly well defined. It is known, for example, that in England and Wales about 30% of *all cases of non-pulmonary* tuberculosis are due to infection with the bovine type; and much the same proportion holds true for Denmark. The findings of the Royal Commission, and later of Stanley Griffith, that only about 1% of cases of *pulmonary* infection were due to the bovine type led to the conclusion that, for all practical purposes, this organism could be ignored as a cause of human phthisis. This belief was generally held for many years, and was not seriously challenged till W. T. Munro in Scotland and B. Lange in Germany reported a considerably higher proportion of bovine strains. Further observations showed that bovine pulmonary infections were much commoner in Scotland than in the south of England, where most of Griffith's early studies had been made, and that they were commonest of all in the north-eastern region of Scotland. Work by K. A. Jensen and his colleagues in Denmark added weight to these conclusions, since, in a study of 3708 strains of tubercle bacilli from cases of pulmonary tuberculosis, the bovine type was found to comprise 5·3%. The question then arose: how does the bovine tubercle bacillus reach the lungs? Griffith and Munro leaned towards the view that in these cases pulmonary tuberculosis was a late manifestation of a previous glandular infection contracted via the alimentary tract. Lange, on the other hand, finding a high proportion of his cases among farm-workers, was inclined to attribute infection to direct inhalation of contaminated dust.

Fresh light is thrown on this problem by the studies in Denmark of Sigurdsson.[1] As he concentrated exclusively on pulmonary tuberculosis his patients were nearly all adults. In his first study he collected information on 566 strains of tubercle bacilli that had been sent for examination between 1932 and 1940 to the State Serum Institute at Copenhagen; of these, 91 (16·1%) proved to belong to the bovine type. Studying the origin of these strains, he found that 67 (40·6%) were derived from the 165 patients who had been living during the two previous years in country districts, 11 (28·2%) from the 39 patients who had spent part of their time in the town and part in the country, and only 13 (3·6%) from the 362 patients who had been living under urban conditions. Further analysis revealed that, among the 67 rural patients infected with the bovine type, 63 had been recently in contact with strongly tuberculous herds of cattle, 4 with herds containing healthy reactors, and none with only tuberculosis-free herds. These observations suggested very strongly that close contact with tuberculous cattle was the chief condition responsible for the development of bovine pulmonary tuberculosis in man.

Milk-borne infection, however, seemed to be largely ruled out, for three reasons: firstly, the clinical features were *those of primary lung disease*, not those of an alimentary infection; secondly, the younger children, who drank milk but who were not in close contact with infected cattle, did not develop pulmonary lesions; and thirdly, pulmonary tuberculosis in adult rural workers who were not living on infected farms but who were exposed to milk-borne infection from these farms was uniformly due to infection with the human type.

Following up this work, Sigurdsson surveyed the population of a rural parish (Grimstrup) in the county of

[1] Studies on the Risk of Infection with Bovine Tuberculosis to the Rural Population, with Special Reference to Pulmonary Tuberculosis. By Jón Sigurdsson. London: Oxford University Press. 1945. Pp. 250. 15s.

content of the same vegetables growing in the same soil varies considerably, and that the differences between them are at least as great as between vegetables in different regions. Nor is he satisfied with the work done on the recovery of iodine from urine and fæces. Finally, he remarks that prophylactic iodine, while reducing the incidence and severity of goitres, does not entirely prevent them; and he says that in some districts the reduction has coincided with a spontaneous decrease.

Simple iodine-lack is no doubt not the whole story. Thus a high content of calcium in the drinking-water reduces the metabolic effects of thyroxine; a high-protein diet can produce goitre experimentally; and many food constituents affect the thyroid. When investigating a goitrogenic factor in rape-seed, Kennedy[9] in New Zealand discovered that allyl-thiourea produced thyroid enlargement in rats; and it was this that eventually led Astwood,[10] of Harvard, to try thiourea as a remedy for thyrotoxicosis. Campbell et al.[11] in Aberdeen then showed that thiourea has a peculiar chemical affinity for iodine: by binding with iodine, it may interfere with the synthesis of thyroxine. Some goitrogenic principles evidently act through the pituitary, for their action is inhibited by hypophysectomy; and perhaps the individual response to them depends on the degree of pituitary activity. The subject is thus complex, and it cannot be said that the pathogenesis of endemic goitre is yet fully understood. But those who connect the condition with iodine deficiency need lose no sleep over this fresh analysis.

Skin-tests in Pertussis

Whooping-cough now occupies first place as a cause of death among the specific infectious diseases of childhood. Some 60–70% of children suffer from it before they reach school-leaving age, and nearly half the cases occur in the pre-school period. Evidence of the development of immunity after natural infection or artificial immunisation has so far been dependent on the demonstration of antibodies in the blood by the estimation of agglutination titres, or by the complement-fixation or opsonocytophagic tests, but such methods—necessitating blood samples from young children—are not practicable outside the experimental field. A reliable skin-test would greatly simplify the study of the epidemiology of pertussis and the assessment of the potency of antigens. So far four substances have been investigated as possible reagents: (1) killed suspensions of *H. pertussis* in phase I; (2) crude extracts of bacterial bodies; (3) agglutinogen; and (4) purified toxin. The first three give an allergic type of reaction similar to the Francis skin-test in pneumonia—i.e., a positive result is taken as an indication of immunity.

Thomson,[12] who investigated the reliability of killed suspensions of *H. pertussis* in varying concentrations, found that these gave non-specific reactions and were of no value in determining immunity or susceptibility, a conclusion which confirmed the experience of earlier workers. By means of an "endotoxin"—a saline extract from ground bacterial bodies—he obtained positive reactions in 85% of children with a history of pertussis, but 30% of control children with no history of infection were also positive. He suggested that the latter results might be due to immunity derived from subclinical infections or from undiagnosed attacks. Strean[13] found that purified toxin extracted from *H. pertussis* by physical methods gave an erythematous reaction comparable to the Schick test in diphtheria—a positive result indicated susceptibility and a negative result immunity. Margaret Kunstler[14] supported his findings on the basis that 65% of children between six and eight months old gave a positive (susceptible) reaction, but Felton et al.[15] found the toxin was of no value in distinguishing susceptible from vaccinated children, and Silverthorne et al.[16] concluded from their investigations that the test in its present form was not a reliable index of susceptibility or immunity.

Agglutinogen was described by Flosdorf and Kimball[17] as a highly purified fraction separated from toxic components by chemical means after sonic disruption of *H. pertussis* in phase I. When inoculated into rabbits it produced high serum-agglutination titres, and intradermal injection into rabbits immunised with *H. pertussis* in phase I resulted in an indurated reaction at the site of inoculation. This reaction did not develop in rabbits immunised with *H. pertussis* in phases III and IV, with *H. parapertussis*, or with unrelated organisms. After standardisation in arbitrarily chosen units based on assay by absorption of agglutinins from immune serum, Felton and Flosdorf[18] used 10 units of agglutinogen in 0·1 ml. of 0·85% sodium chloride as the intradermal dose for children. Three types of reaction were observed at the site of injection:

(1) *Positive-immune* (P.-I.).—A well-indurated reaction (with or without erythema) 20 mm. or more in diameter at either ½ hour or 24 hours or both.

(2) *Weakly Positive-immune* (W.P.-I.).—An indurated reaction (with or without erythema) not exceeding 20 mm. in diameter at either ½ hour *or* 24 hours, but at least 10 mm. in diameter at either time or both.

(3) *Negative-susceptible* (N.-S.).—No indurated reaction at either ½ hour or 24 hours beyond an area 10 mm. in diameter.

Induration, not erythema, was taken as the determining factor in classifying the reactions. There were no untoward local or systemic effects after injection; the reaction faded quickly and usually disappeared within 36 hours. In this first investigation 94 babies aged six to fourteen months were used as controls. All gave the N.-S. reaction. Of 305 vaccinated children, 23 were N.-S. (subsequently they were found to have been immunised with a vaccine of questionable potency), 112 were classified as W.P.-I., and 170 as P.-I. Of children with a history of pertussis (not necessarily accurate) 21 were N.-S., 38 were W.P.-I., and 52 were P.-I. In a further series Flosdorf et al.[19] obtained similar results. Of 122 "control" children aged six to fourteen months, only 1 gave a positive reaction; 89% of children with a history of pertussis and 92% of vaccinated children were classified as P.-I. or W.P.-I. Although agglutination titres done at the same time as the test were negative or nearly so to 49 years and decreases rapidly until 70. Accordingly the mortality in women is 143% of the estimated mortality, and in men 288%, or more than double the normal. Bechgaard postulates a sex difference which causes the circulatory system to be more resistant to raised blood-pressure in women. The prognosis becomes worse with increasing age owing to associated myocardial degeneration, and it is bad in malignant hypertension.

Although Bechgaard's material consists of patients who had a blood-pressure of 160/100 mm. Hg, or a systolic blood-pressure of 180 mm. Hg at the first examination, he defines the upper limits of normal blood-pressure as 140/90 mm. "in agreement with most of the recent investigations." Accordingly, he regards people who have a blood-pressure of more than 140/90 mm. as hypertonics, even if they are over 40 years of age. He adds, correctly, that "with this limit a very large number of older people (in case of the oldest more than 50%) are regarded as hypertonics." This would not be accepted by British and American observers, who regard as abnormal in people over 50 a blood-pressure of 170/105 mm. Hg taken under proper precautions on at least three occasions.[8]

DETERMINING THE TIME OF OVULATION

IN the investigation of cases of infertility it is often important to ascertain the time of ovulation. The methods used for this purpose include examination of the vaginal smear and the cervical mucous plug, biopsy of the endometrium, and, more recently, charting of the temperature, which theoretically should show a slight fall at the time of ovulation.[9] Unfortunately this last method, which has the attraction of simplicity, does not seem to be proving as accurate as was hoped.

Farris,[10] of Philadelphia, proposes another way of establishing the time of ovulation. He finds that if the patient's urine is injected into an immature white rat, the rat's ovaries become hyperæmic if ovulation is taking place, but not otherwise. The first morning specimen of urine is used, and 2 ml. is injected subcutaneously into each of two animals. The animals are coal-gassed after two hours and the abdomens opened. The degree of redness of the ovaries is compared with a standard colour chart. Farris attributes the hyperæmia to the action of pituitary gonadotrophin, which shows a peak rise at the time of ovulation.

This new test is certainly of scientific interest, and should prove valuable in laboratories equipped to perform it. The reading of the reaction, however, is by no means easy, and Farris admits that abnormal reactions are fairly common. We still await the simple, cheap, reliable, easily interpreted test for ovulation which gynæcologists would find so useful.

FUTURE OF PREVENTIVE INOCULATIONS

THE list of diseases for which satisfactory preventive inoculations have been discovered is ever lengthening. Dr. H. J. Parish, in his presidential address to the epidemiological section of the Royal Society of Medicine on May 23, reviewed current immunological procedures for each disease in turn. In the prophylaxis of diphtheria and tetanus, typhoid and typhus, smallpox and rabies, yellow fever and cholera, the use of an appropriate vaccine or toxoid is universally practised. Evidence of the value of pertussis vaccine is still somewhat contradictory, and the short-lived immunity obtained from influenza vaccine at present limits its application. Promising preliminary reports are appearing on the use of an attenuated mumps virus, and an effective attenuated measles virus may in time be produced. Dr. Paris believes that advances depend on close coöperation between the immunologist, the bacteriologist, and the chemist. Many unsolved problems remain to be tackled. Knowledge of the basis of racial and species immunity (inherent non-susceptibility) is entirely lacking. There is no explanation of the immunity of man to avian tuberculosis or of dogs and goats to tetanus. Again, we know that immunisation of the pregnant mother with diphtheria prophylactic raises the circulating antibody titre of the child, but although passive immunity can be conferred on the mother by injection of diphtheria antitoxin in horse serum, these immune bodies do not pass the placental barrier. Most exotoxins can be measured quantitatively and qualitatively, and they are relatively stable substances; but endotoxins are in a different category and our present understanding of their action is much less complete. Dr. Parish suggested that in the near future much effort will be expended on elucidating the antigenic structure of organisms and preparing pure stable antigens capable of exact measurement and less likely to produce allergic manifestations. Other paths of research are the use of new mineral salts to combine with antigens—such as the aluminium-phosphate diphtheria toxoid of Holt—and careful assessment of the antigenic potency of strains used in the preparation of vaccines and toxoids. The work of Barr and Glenny,[1] showing that higher antibody titres can be obtained with two doses of A.P.T. at a three-monthly interval (instead of the usual one month) reminds one that we do not yet know the optimum spacing or dosage of diphtheria toxoid.

There is little hope, in Dr. Parish's view, that artificial immunity will be obtained without recourse to parenteral injections, and the ideal of all antigens being administered in one single inoculation is far in the future. The growing practice, however, of combining certain antigens (e.g., diphtheria and tetanus toxoids with pertussis vaccine) should, he thought, become more common, for it reduces the number of injections without apparently reducing the immunising value of each antigen.

OUT OF POCKET

ENGLISH local government has a fine record of unpaid service. Those taking part have given generously of their leisure and energy, and in the past they have not grudged the expenses that went with their duties, for they were usually in a position to afford them. Today, however, with altered social and economic conditions many of those best fitted to serve on local councils can only do so at a sacrifice which we are beginning to feel it is unfair to ask them to undertake. The interdepartmental committee which have just reported[2] to the Ministry of Health and the Scottish Home Department on the expenses of members of local authorities confirm these uneasy fears. From the evidence they received they gained the impression that some members were suffering undue hardship, and that suitable candidates were being deterred from standing for election by fear of expense and loss of time. They have therefore recommended that local authorities should have power to pay allowances to councillors who lose remunerative time in attending meetings and carrying out their public duties, and that councillors should be entitled to be paid travelling expenses and subsistence allowances. The principle involved is of importance to the new health service, which will depend so much on the wisdom and generosity of those who sit on its committees and boards. If we are to have practical members chosen from among working people—whatever their work may be—it is important that no-one should be hindered from accepting office from fear of out-of-pocket expenses.

ibe, to determine the incidence of tuberculous infection. o fewer than 680 out of the 745 persons in the parish ubmitted to examination, which included a tuberculin est, radiography of the chest, and bacteriological nvestigation wherever pulmonary tuberculosis was uspected. For purposes of analysis the subjects were ivided into three groups, according to whether they ad been in contact with strongly-tuberculous herds, pparently healthy reactors, or only tuberculin-negative erds. In the first group 4·8%, in the second group ·8%, and in the third group none, showed evidence f pulmonary tuberculosis (not necessarily active). A econd survey was carried out on 100 families living on arms where there was a large amount of tuberculosis n the cattle and on 100 families living on farms where ll the cattle were tuberculin-negative. In the former roup 3·0% of persons showed evidence of pulnonary tuberculosis, and in the latter group only ·3%.

The general conclusion reached from these results is hat in Denmark pulmonary tuberculosis of bovine rigin is mainly due to close contact with tuberculous attle, and that infection is contracted by inhalation ather than ingestion.

STANDARDS OF MEDICAL EDUCATION IN U.S.A.

ONE of the subjects discussed at the meeting of the New York Academy of Medicine in April was how to improve medical education.[1] Dr. Carl Eggers pointed out that it was in 1904 that the first real steps were taken to coördinate the various educational systems under the committee of medical education created by the American Medical Association. This was followed by the gradual elimination of inferior schools, and in 1910 the first classification of medical schools was published. The United States now has 69 schools which offer the complete course, and 8 which offer only the first two years of medical training.

Much attention has been given in the last few years to the status and education of the general practitioner, who is justly called the "forgotten man" of medicine. A good working knowledge of the body as a whole, early manifestations of diseases such as cancer and tuberculosis, acute medical and surgical emergencies, and obstetrics calls for considerable postgraduate experience. But in the light of English custom it is surprising to learn that in America before the war 18 months or 2 years of house-jobs was considered normal, and the 12 or 9 months during the war was thought to be a very short time.

Concerning the teaching which residents receive, it is more and more being realised that recently qualified doctors are not in residence only to benefit a particular hospital, but to learn as well. Dr. David Seegal criticised the present system, pointing out that 87 out of the 111 hospitals in greater New York have no university affiliations. Two major attempts had been made to alter this state of affairs, one in New York and the other in the State of Michigan. The chief difficulty in both cases seems to have been that the available staff did not have enough time to devote to teaching, and in New York two hospitals were chosen for study, each one nominating a medical and surgical teacher (usually doctors who had just finished their residencies) who spent a third or half of their time in teaching and study. After a year's trial this scheme seems to have worked well, and is generally popular. The Michigan plan has been an altogether larger design; much seems to have been done to improve the education of the doctors in this State. The central authority is the university, to which any hospital can ask to be affiliated. The hospital must then agree to provide a minimum teaching programme for the benefit of its residents, which includes daily ward rounds, X-ray and pathological conferences, and so forth. In return the university provides lectures in the various specialties. The great advantage of this scheme is that it not only caters for the man who wishes to specialise but improves the teaching capacity of the smaller hospital. The urgent problem is now to make general practice more attractive by limiting the process of infiltration which has gradually been removing pieces from the practitioner's frontier; such innovations as the health centre should help.

PROGNOSIS OF RAISED BLOOD-PRESSURE

As early as 1913 Janeway[1] called for caution in giving a bad prognosis in cases of raised blood-pressure. He demonstrated that many patients with essential hypertension lived for years in good health and were completely fit for work. Benni,[2] who reported that 112 (77%) out of 146 patients with hypertension died after 4 to 14 years, admitted that his figures were not quite significant since many of his patients were aged seventy years and upwards. Blackford et al.[3] followed up 222 patients out of 401 from 5 to 11 years after a systolic blood-pressure of more than 175 mm. Hg had been found. Of these, more than half (70% of the men and 39% of the women) died between the first and second examinations. The average duration of life after discovery of the hypertension was 32 months. The death-rates for moderate and severe hypertension were the same. Russek[4] noted that if the diastolic pressure was normal expectation of life was not adversely affected by a raised systolic pressure. Rosling,[5] who followed up 450 patients with raised blood-pressure (the limit being 160 mm. Hg and over), found that of 102 of them who had essential hypertension without complications only 30% were dead 8 years later. Wagener and Keith[6] grouped hypertensives according to the changes of the vessels in the fundi. In the four groups described by them they examined 209 patients, and in the follow-up 5–9 years later 40%, 65%, 92%, and 99% were dead.

In his recent monograph Poul Bechgaard[7] has reported on a follow-up of over 1000 hypertonics. His material consists of 325 men and 713 women who at the first examination had a blood-pressure of 160/100 mm. Hg or over, and 97% of them were examined very carefully 4–11 years later. The patients were mainly working men and women between 40 and 69 years of age, the age-group 50–59 being the largest. Bechgaard emphasises as one of the main characteristics of arterial hypertension the well-marked lability of the blood-pressure and its increased amplitude. Electrocardiographic examinations showed signs of myocardial disease in 30%. Cerebral hæmorrhage was found in 8·3% and hypertensive encephalopathy in 3·5%. Malignant nephrosclerosis was found in only 13 patients at the second examination, 11 of whom had already had symptoms at the first. In Bechgaard's view malignant nephrosclerosis may be due to a number of different conditions, such as psychological strain, infection, arteriosclerosis, syphilis, or lead poisoning. From his figures, the prognosis of essential hypertension, judged from the death-rate, appears to be very good indeed. It is remarkable that 41% of the men and only 22·4% of the women died during the period of observation. If the normal mortality for the (Danish) population is taken as 100%, Bechgaard calculates the excess mortality in his series as +188% for men and +43% for women of all ages. The excess mortality is high up

Modern Care of Old People

I

A NEW OUTLOOK IN THE WARDS

The West Middlesex Hospital

NEGLECT of the old in institutions is rather the rule than the exception. Several things have contributed to this dismal situation: want of staff, want of buildings, want of equipment, even want of paint. But the outstanding trouble is want of imagination in the doctors and nurses who look after them. Some infirmaries are still scrap-heaps to which the medical staff of acute wards send any case which seems "not worth treating"; and when doctors discard patients in this bored and defeated spirit, nurses can hardly be blamed for feeling they are scarcely worth nursing.

In the West Middlesex County Hospital a new spirit has been developed in the reablement of elderly people with long-term ailments. Patients are classified according to their condition, and are actively treated in a hopeful atmosphere. The geriatric wards, under Dr. Marjory Warren, are treatment wards equipped to meet the special requirements of the aged.

Probably no condition is so hopeless or so chronic that it cannot be eased, perhaps ameliorated, by the resources of a good doctor; and it is precisely in the care of such patients that the nurse achieves her highest skills.

A NEW CHANCE

The West Middlesex is a large general hospital, of over 1200 beds, which in the old days shared its site with a poor-law infirmary. A medical officer, whose chief work lay in the hospital, attended daily to initial medicine-cards, and to see any of the old people whom the sister thought not so well. The wards were painted in the chocolate and dark green shades beloved of guardians; the pendant electric lights were ill placed, shining in the eyes of sick patients and giving poor light to those wanting to read. Every ward had its mixture of healthy elderly patients who could get up; sick patients needing treatment or dressings or both; senile, incontinent, and demented patients, some of whom were restless and disturbing to others; old people, young people, and even children.

In July, 1935, the infirmary was taken over by the hospital, under the Public Health Act of 1929; and this was recognised as an opportunity. It was not easy, however, to know where to begin; the wards were in the Victorian tradition, equipped with low black iron beds and lockers which had to be shared between two patients, and fitted with ordinary domestic doors, partitions which prevented the easy transfer of beds from one section to another, and many other awkwardnesses. Indeed these wards had never been built or equipped to take sick patients, but to house the elderly in dormitory fashion. Extravagant outlay was not possible: it was a question of making the best use of what lay to hand. A careful survey was made of each of the hundreds of inmates, and scores of their relatives and friends were interviewed before reforms were planned. Early in 1936 the first steps were taken in building up the present geriatric unit.

Patients were classified afresh; the younger ones—that is, the under-60's—were separated from the old, who range (especially in the women's wards) up to 96 and 97. An early change was in the colouring of the wards. Walls were painted cream, and comfortable high nursing beds painted in pale colours were bought for the sick; low beds suitable for use of ambulatory patients, and equally easy to work, replaced the old black iron ones. The frames carrying doors were removed from the central partitions, leaving a not ungraceful archway through which beds could readily be pushed. Lockers of a good type, one for each patient, rep the old clumsy kind.

By 1938 it had become possible to replace the doors of the ward by swing doors which nurses with hands could push open without fumbling for a door and through which a bed could pass without being dismantled. At this time, too, the pendant lights were exchanged for opaque bowls set above the beds, from which a bright but gentle light was thrown upwards.

Scarlet top-blankets and light-coloured bedspreads and screen-curtains also helped to change the look of the place, and relatives were encouraged to visit, and to bring flowers to, the patients. This different atmosphere interpreted a difference in the care of the patients, which has been steadily growing through the years.

The old-age groups, in the course of time, were classified still further. Those with acute illnesses were sent to wards where their conditions were investigated and treated. Restless patients, or those liable to lean to one side and fall out of bed, were nursed in wards with cot-beds. Ambulatory patients, including those fit for discharge and waiting for a vacancy in a residential home or hostel, and also those who need to stay a little longer in hospital, and yet who do not need to stay in an acute sick ward, are grouped together in a ward for up-patients. Finally, there are wards for the incontinent.

The decision to put all the incontinent women together in one ward was made in an experimental spirit, for it was thought the nursing staff might find it objectionable. The medical director and matron, however, agreed to give it a trial; and the sister of the ward found in it an opportunity for some remarkable work. Since March, 1936, the ward has had only three sisters in all, and the present sister has been in charge for over four years. Some 45 incontinent women fill the beds, yet there is no unpleasant smell and no atmosphere of depression; and though most of the patients are senile the atmosphere of this ward is as cheerful as that of the rest.

Nursed according to a routine worked out by an interested and experienced sister, every patient is made comfortable, and none fears she may annoy her neighbour, or worse still her neighbour's visitors, as may happen when a solitary incontinent patient is nursed in a ward with others. The patients are thus spared the feelings of guilt and unhappiness which the incontinent patient nursed in a busy general ward so often develops. The ward is equipped with 900 draw-sheets and adequate quantities of other linen, which greatly eases the nurses' problem. Under these favourable conditions the sister finds she is able to train some patients back into continence. A sister undertaking this difficult and important work is at one of the growing-points of her profession; and in this hospital she has the prestige her work deserves.

In the cot-bed ward for restless patients, too, the sister is keenly interested in their progress.

OUTLOOK

Perhaps the greatest change has been in the prognosis of the patients. It is assumed from the start that they want to get well enough to go back either to their own homes, or to the residential homes from which they came; and 30% of them do. Patients admitted after a stroke, for example, are not left lying in bed until their limbs become fixed in permanent contractures; they are encouraged to take an interest in their condition, to exercise the affected limbs from the day of admission or as soon as they are able to do it. After a few weeks they get up and practise pulling themselves upright from a chair placed at the foot of the bed, by holding on to the bed-rail; later they learn to walk a few steps with help, and finally they go down to the gymnasium, where they practise with the walking-machine, learn to go up and down steps again, meet and talk with others showing like disabilities and progress, and develop a healthy spirit

Special Articles

HEALTH IN 1945-46

The Ministry's Annual Report

THE transitional period between war and peace, though cking the historic appeal of the war years, has proved ne of peculiar difficulty for our health services. The eturn of vast numbers of soldiers and prisoners-of-war, any of them convalescent from or carriers of a variety f infectious and tropical diseases, set an unprecedented ublic-health problem, and Sir Wilson Jameson, the hief medical officer of the Ministry of Health, whose eport for 1945 is for the first time incorporated with he Ministry's annual report,[1] is justly proud of the uccess of his officers in preventing the spread of such angerous invaders as typhus, smallpox, and malaria.

VITAL STATISTICS

The birth-rate, which had reached 17·7 per thousand ving in 1944—the highest since 1926—declined to 5 9; but this was obviously the result of the departure f large forces overseas. The death-rate was 11·4, and he civilian death-rate, which included violent deaths f civilians due to war operations, was 12·6 per 1000 —slightly better than the average of 12·7 for the three receding years. The rising proportion of old people n our population was reflected in increases in deaths ue to diseases to which they are most liable. Thanks o the small amount of traffic, road accidents accounted or only 4572 deaths, the lowest number for many years, hile fatal war casualties amounted to 5239, almost all f these occurring in the first third of the year.

INFECTIOUS DISEASES

Here the striking features were the continued fall in the mortality from measles and scarlet fever in children, a repetition of the fortunate experience of the war years as regards influenza and the enteric fevers, and fewer deaths from pneumonia, but more dysentery.

Influenza.—The fear of a reappearance of the pandemic of 1918 was not fulfilled, and there was no need to embark on the large-scale plan of immunisation which had been prepared. Only 2686 deaths were recorded from this cause, the lowest total for thirty years.

Diphtheria.—Both notifications and deaths reached new low records, with totals of 18,596 and 722, compared with 23,199 and 834 in 1944. Since mass immunisation was introduced in 1940 the deaths in children aged 2–15 years have steadily fallen, the rate in 1945 being 6·7 per 100,000, against 28 in 1941. At ages under 2 and over 15 years there has been a slight rise.

Measles.—Notifications reached the highest figure since 1940, when notification began, yet out of 446,796 cases there were only 729 deaths, a fatality-rate of 0 16%, about a seventh of that of whooping-cough.

Cerebrospinal fever.—The 555 deaths (out of 2063 notifications) were fewer than in any year since 1928 except 1939.

Poliomyelitis.—Notifications (784) were higher than the previous year (464) but little more than half the figure for 1938, the epidemic year.

Intestinal diseases.—The remarkable freedom from typhoid fever continued, but notifications of dysentery again rose, to 16,278; how far this was because of better recognition is unknown; in some 87% the causative organism was *Shigella sonnei* and in the remainder mostly *Sh. flexneri.* Of the food-poisoning outbreaks investigated nine-tenths were apparently due to salmonella infections; the danger of insufficiently cooked duck's eggs was again demonstrated.

Jaundice.—Only small outbreaks of epidemic hepatitis were reported in the year, and there were no cases of jaundice following prophylactic or therapeutic inoculation; but the last battles of the war left an aftermath of post-transfusion jaundice, the incidence in one series being 82 per 1000 persons transfused. Weil's disease was the certified cause of 29 deaths, and the case-mortality seems to be about 10%.

Tuberculosis.—The downward trend of the mortality among the population as a whole, interrupted in the war, was resumed, but there was an increasing shortage of beds for treatment, mainly because of shortage of nurses and domestics.

Venereal diseases.—By importing infection from abroad and increasing the young adult population, demobilisation raised the incidence of both syphilis and gonorrhœa, but the large number of people who attended the clinics for examination and were found to be free from infection showed a satisfactory awareness of the value of early treatment.

MATERNITY AND CHILD-WELFARE

The infant-mortality rate (46 per 1000 live births) was slightly higher than in 1944, while the stillbirth-rate (28 per 1000 total births) remained the same. Maternal mortality reached the lowest level ever recorded (1·80 per 1000 total births), and if deaths following abortions are excluded the rate was 1·47 per 1000. Considering the shortage of staff and the resulting pressure on the maternity services generally this was a highly creditabl record.

LABORATORIES

The year saw the beginning of the conversion of th Emergency Public Health Laboratory Service into permanent structure. Staffing presented considerabl difficulties, because few trainees had been permitted during the war, and not many Service pathologists ha the necessary training and experience for these civilia posts. An important step initiated was the establishmen of a central public health laboratory in the premises o the Government Lymph Establishment at Colindale. The Medical Research Council, which had previously administered the emergency public health laboratories in the provinces, took over control of those in the London sectors from the Ministry of Health, but it was thought advisable to leave the supervision and coördination of central London laboratories in the hands of the London County Council.

THE AGED AND CHRONIC SICK

The ten hospital surveys, summarised in the report by Dr. T. S. McIntosh, revealed a serious deficiency in beds (estimated at at least 40%), the obsolescence of many of the existing buildings, a shortage and maldistribution of specialists, and the need for more special centres. The plight of the chronic sick was emphasised in every report, and one refers to the "masses of undiagnosed and untreated cases of chronic type which litter our public assistance institutions."

Sir Wilson Jameson points out that the medical student has in the past received too much of his clinical instruction on patients who are acutely sick. This has tended to make doctors unduly pessimistic as to what can be done for the chronically sick and aged. Steiglitz in America has remarked that the aged sick, simply because they are old, are too often denied modern treatment, though in fact old people tolerate surgery, for example, quite well, and with adequate medical and nursing attention often make surprising recoveries from serious injuries and illnesses. Dr. E. L. Sturdee calls for research into suitable accommodation for the aged and also into the early diagnosis and special treatment of those diseases which are not fatal but may lead to years of incapacity unless they

Reconstruction

POSTGRADUATE EDUCATION IN THE SERVICES

P. K. FRASER
M.D. Glasg.
SURGEON COMMANDER ROYAL NAVY

A NEW era of medicine is opening, and the time seems ripe for a complete fusion of the civil and Service aspects of the profession.

It may be asked what was wrong with pre-war medicine that necessitates a new era. Similarly we might ask what was wrong with the horse-drawn omnibus at the turn of the century. The answer is Nothing. As the horse gave way to the motor, so medicine is adapting itself to changing times and newer horizons. The situation is neatly summed up by R. L. Wilbur, of Stanford University, U.S.A., when he says:

> "Specialization is inevitable and group practice desirable. The future of medicine will be played out around medical centres now existing and to be established, where all the institutions and workers in medicine come together and make a pool of medical knowledge." [1]

Some will object to this emphasis on specialisation, but the following remark by K. T. Compton puts it in perspective:

> "In the early days all the sciences were combined together frequently in the same individual. Later the various specialties had a tendency to run their separate courses. Now we find them coming together again for mutual support." [2]

If we are to produce men of the calibre of the older school of general practitioners and consultants, with their breadth of outlook in all the sciences and their understanding of medicine as related to human suffering, compartmentation must be broken down and integration fostered. Carried to extremes, specialisation merely provides a series of doors at which the patient knocks in the hope of finding the right one. The specialties must be based on a broad general understanding: after all the tallest New York skyscrapers have a pretty wide foundation. In a growingly complex field, we must, as Compton says, come together for mutual benefit and support.

HOUSE-APPOINTMENTS

In Service as in civil medicine we have the problem of the gap between the general practitioner (general-duty officer) and the hospital. In civil life some practitioners demand the right to treat their own cases in hospital and some even specify special G.P. hospitals. There is something to be said for this; for, as Osler said, "the general practitioner does the work and the consultant does the writing and collects the fees (or the kudos)." However, having practised in and out of hospitals in civil and Service medicine, I can say emphatically that to carry out such schemes would produce an administrative bedlam. What these men want is access to the *material* in hospital, and this can be achieved by regarding all hospitals as postgraduate centres with ward rounds, demonstrations, and clinical meetings.

To organise teaching—or, to put it in another way, presentation of material—would require changes in staffing; and as Naval hospitals are the only Service hospitals with which I am familiar I shall take them as an example.

In the large base hospitals the senior establishment is simple and compact. The senior officer has his two heads of the divisions of medicine and surgery, and after them come the specialists in charge of wards. No business expert could quarrel with this. Below this level, however, there is dissatisfaction. There are no definite house-physician or house-surgeon posts and there is considerable insecurity of tenure. The absence of appointments as resident medical (or surgical) officer is another outstanding lack. House-posts should be definite, and men should be appointed house-physician or house-surgeon for a stated period—e.g., six months. Posts at the R.M.O. level would give the holder access to all the work of the division, and all records would pass through his hands for final approval. He would help and direct the house-officers and would arrange the teaching programme throughout his division.

At this point we can raise the burning question of adequate clerical assistance. During the war the typist-stenographer played a valuable part in conserving man-power, and this type of economy is at least as necessary now as it was then. Adequate office equipment is essential in any modern organisation, and particularly in hospitals where the records form the patient's main safeguard in future illnesses or in questions of compensation. Further, these records are invaluable in any research project. The specialist should be left free for the duties of his office and not saddled by work which belongs rightly to a junior clerk.

SERVICE AND CIVILIAN

Integration with the civil side can best be arranged at the specialist level. Most Service hospitals are within reach of their civil counterpart, and the Service specialist should be appointed as associate to his civilian "opposite number," who will assume responsibility for his continued training. The medical services of the Forces have always been part of the medical services of the nation, and no opposition to this plan need be expected: indeed it has been tested unofficially over many years, and merely requires official sanction and wider scope. With the coöperation of the local consultants a teaching programme embracing all medical facilities in the district could be arranged.

The outstanding gap in these proposals concerns the man seeking highly specialised and personal tuition not available locally. Usually he is a candidate for a higher degree or diploma, and his case could best be dealt with through a central office as at present. Here the Postgraduate Medical Federation is the natural body to approach, though unfortunately its activities are confined to the London area. The ideal for most people is appointment as personal assistant to one man who undertakes the teaching and direction of his pupil.

Eventually, perhaps, we could have overseas postgraduate study at the more senior levels. During the war many pleasant and valuable contacts were made with the best brains of our Allies, and it seems sad that this great broadening influence should come to an end. As Levine, of Boston, has put it, "we little realise the constant acquisition in knowledge that we experience from the casual and more spirited conversations with our intimate colleagues and medical friends. This is one of the most characteristic and laudable aspects of our great profession." The United States Navy has already drawn up an ambitious programme of postgraduate teaching which merits close study.

I am indebted to the Medical Director-General of the Navy for permission to publish this article.

[2] *Ibid*, 1946, 131, 77.

AN exhibition of labour-saving devices for use in hospitals, organised on behalf of the Ministry of Health by the British Electrical Development Association with the coöperation of the British Gas Council, is being held at the Empire Tea Centre, 22, Regent Street, London, S.W.1, from July 15 to August 2. The morning sessions are being reserved for hospital representatives, but the public will be admitted every weekday afternoon, from 1 to 6.

Exercises in the gymnasium.

The gymnasium is a very simple affair—merely an empty ward, well warmed with hot pipes, and with a bar made from broom-handles running round the walls, plenty of chairs, and some rib-stalls and a small flight of steps made by the hospital carpenter. No expensive equipment is needed: simple apparatus is the most successful. The only piece of bought equipment in constant use is the iron walking-machine which takes the patient's weight along the length of his forearms, and gently compels him to follow its progress step by step. The gymnasium can also be used by the physiotherapist or gymnast for classes taking breathing exercises, and for children needing physical training or re-education of muscles; while taking a class she can keep an eye on seven or eight old people practising standing or walking, ambling up and down the steps, or doing other exercises.

Occupation in a treatment ward.

ADMISSION AND PROGRESS

Special thought has been given to the placing of new admissions, and to the progress of a patient through different types of ward. There are two admission wards: one contains only cot-beds, and receives patients likely to endanger themselves by falling out of bed, at least in their early days; the other contains only open beds, into which old people not likely to need a cot-bed are received. Patients may graduate from cot-beds to open beds as they improve. If, after careful study, a patient proves to need more nursing than medical care—if she has an incurable carcinoma or an advanced progressive nervous condition, for example—she may go to a small ward with other similar types of case. Admitted to an open-bed ward, the patient normally never sees the cot-bed ward at all. If her condition can be improved, she is treated and ultimately sent home. If she has no home, as soon as she has made enough progress, she goes to the up-ward, to wait for a vacancy in a residential home. Thus her time in hospital is a steady progress, with the hope of discharge at the end of it. Even if she comes back again later, she has had so many more months of normal life with her family, and she returns to hospital in a hopeful spirit, willing to help to mend herself again.

The up-ward is a cheerful sort of club, where anyone who wishes helps to lay and clear the table, and to tidy the wards and dayroom. The big Victorian dayroom, with ample windows, is lined with easy chairs—some tubular, some windsor, some cane, but all easy. Headphones can be plugged into the wall; and books and papers and flowers can be enjoyed in the well-warmed air. If a patient wants to spend part of the day in the ward quietly beside her bed, writing letters, or lying down on top of it, nobody will stop her. Most of the patients are engaged in knitting, sewing, or some other kind of occupational therapy, and all look alert and purposeful; the deadly apathy of the institutional "inmate" is nowhere to be seen.

Two wards might be expected to show a less hopeful spirit: the cot-bed admission ward, and the ward for the incurable with cancer and other serious diseases. In fact, the admission ward looks as cheerful and comfortable as the rest, and the incurable ward is astonishingly free from fear and despair. Several of the patients make felt toys in gay colours, the materials and patterns being supplied by the occupational therapist. They are much interested in this little craft, and are ready to explain that they had never tried it before. In the men's ward, string-seated stools and knotted dog-leads take the place of sewing, and excite the same interest.

A ward in the new tradition.

THE NURSES

The most striking thing about these wards for the chronic sick is the attitude of the nursing staff. They are keen, lively, conscious that they are exercising themselves fully in their profession, and proud of the results. A bedsore is regarded as a disaster, and nursing students learn the real technique of prevention of bedsores, on helpless or paralysed, thin, old patients whose tissue-paper skin needs minute care. This state of mind in the nurses is not the creation of a moment: it has grown gradually as the inspiration to be found in this kind of work has been revealed to them. The West Middlesex Hospital is now well fitted to offer State-registered nurses a certificate in the care of the chronic sick. Such active nursing is the outcome of active doctoring.

The up-ward.

In England Now

A Running Commentary by Peripatetic Correspondents

I WISH I were one of the better sorts of invalid, the ntellectual type. Lancelot Hogben in bed for a month rote *Mathematics for the Million.* Robert Lynd while n last winter wrote many an essay full of charm and himsy for the Saturday Page of the *News Chronicle.* ur own professor retires on an average twice a year ith what he terms bronchitis; he remains in bed about week, and during this time performs that comprehensive eat known as "keeping-up-with-the-literature," reviews hree books, writes two witty articles for the lighter olumns of the learned periodicals, one stinging letter o the *Times,* and prepares three or four addresses, ectures, and surveys.

How do I pass the day? Eight to nine o'clock, bath, ace-fixing, schizophrenic indecision—blue or pink yjamas? Ten to eleven newspapers. Eleven to one 'clock gossip with kind colleagues who pop in to pass the ime of day. One to three o'clock detective story, sleep. nd so on throughout the unproductive day. The only emotely intellectual effort of the whole twenty-four ours is the designing of fantasy meals—grilled lamb utlets, camembert cheese, mushrooms on toast, crêpes uzette, complete in the blue flame of old brandy. Do antasy meals stimulate the gastric juice? I imagine so, udging by the lack of gastric peace which is my lot at resent. If this is true does the opposite work? Here erhaps is the idea which places me right in the front anks of intellectual invalids; here is a new treatment f peptic ulcer. Let the ulcer patient eat what he likes, hen he likes, and where he likes, but let him meditate very two hours on milk, mashed potatoes, and poached ggs. Here's an idea worthy of research, and by Saint Sippy! let me be the first subject of the experiment.

* * *

The Webbs, as much as any, are responsible for the design of the new society which we have been and are now building. None have contributed more to its theory and practice in social security and constructive public health, in nationalisation, in industrial relations—and in converting the public mind to the idea of the positive welfare State as opposed to the police and fire-brigade State of Victorian England.

What manner of folk were they? Despite the autobiography (least personal I have read) and the life of Beatrice I still find them very difficult to picture and rather intimidating. Neither do the first two "Webb Memorial" lecturers, R. H. Tawney and Margaret Cole, indulge our curiosity ("beware of dilletantism!", Tawney imagines Beatrice admonishing; "above all, no intimacies," echoes Sidney), and in true Webb fashion they keep their noses to the grindstone and confine themselves strictly to the *work* of their heroes.

Were there ever such workers? Tawney mentions 45 volumes, including the ten on local government, apart from the pamphlets (Sidney wrote 47 of these for the Fabians alone), articles, essays, and introductions to works by other writers. All this on top of an intensely active life in the Fabian Society, Labour Party, L.C.C., Parliament, and L.S.E. Luckily they had private means: Laski mentions somewhere that fifty years of solid and systematic writing brought them in less than £100 after their secretarial expenses had been paid.
